Extended Method of Moments with Application to Derivative Pricing

Abstract

The Generalized Method of Moments (GMM) has been introduced to estimate parameters defined by conditional moment restrictions. This paper considers the estimation of other conditional moments. We distinguish two cases depending whether the conditional moment restrictions are for a given value of the conditioning variable (limited information approach), or if they are uniform with respect to the conditioning variable (full information approach). We derive the nonparametric efficiency bounds for limited information, full information, or mixed approaches, and describe estimation methods to reach the bounds. The first method can be interpreted as a GMM method with an extended set of moments, which explains its name, i.e. extended method of moments (XMM). The second method is an information based approach. Finally we discuss the application to efficient pricing of derivative assets.

Méthode des Moments Étendue avec application à la valorisation de produits dérivés

Résumé

La méthode des moments généralisée (GMM) a été introduite pour estimer des paramètres définis par des conditions de moments. Dans ce papier nous nous intéressons à l’estimation d’autres moments conditionnels. Nous distinguons deux situations selon que les restrictions de moments conditionnels sont pour une valeur donnée de la variable conditionnante (approche à information limitée), ou si elles sont uniformes par rapport à cette variable (approche à information complète). Nous dérivons les bornes d’efficacité non-paramétrique pour ces deux approches et décrivons des méthodes d’estimation permettant d’atteindre ces bornes. Dans certains cas, la méthode s’interprète comme une méthode des moments généralisée avec un ensemble élargi des moments, d’où le nom de la méthode: extended method of moments (XMM). Finalement nous discutons l’application à la valorisation efficace de prix de produits dérivés.

Mots clés: Méthode des moments généralisée, efficacité non paramétrique, information complète, information limitée, valorisation d’options, volatilité stochastique, prime de risque, instruments faibles.

# 1 Introduction

The Generalized Method of Moments (GMM) has been initially introduced by Hansen (1982), Hansen, Singleton (1982) to estimate parameters defined by Euler conditions. Typically in a Consumption based CAPM [Lucas (1978)] the restrictions at date \( t \) are:

\[
P_{i,t} = E_t \left[ p_{i,t+1} \delta U'(C_{t+1}; \gamma)/U'(C_t; \gamma) \right], \quad i = 1, \ldots, n, \tag{1}\]

where \( U \) is a utility function, \( p_{i,t} \) the observed prices of the \( n \) financial assets, \( C_t \) the consumption and \( E_t \) denotes the conditional expectation given the available information including the lagged values of prices and income. The parameters of interest are the preference parameter \( \gamma \) and the psychological discount rate \( \delta \). The model is semi-parametric. GMM focuses on the estimation of \( \theta = (\gamma', \delta)' \) and disregards the nuisance parameter, that is the joint conditional distribution of prices \( p_{i,t+1}, i = 1, \ldots, n, \) and consumption \( C_{t+1} \). Recently different approaches, called empirical likelihood, minimum chi-square or information based approach, have been proposed to simplify the derivation of a GMM parameter and to improve its finite sample properties\(^1\). The basic idea is to estimate jointly the structural parameter \( \theta \) and the nuisance infinite dimensional parameter under the moment restrictions.

However the Euler restrictions (1) are not only useful to test a structural equilibrium model. They are also used in Finance for pricing derivatives. More precisely the Euler condition is considered as a pricing formula:

\[
P_{i,t} = E_t \left[ M_{t,t+1}(\theta)p_{i,t+1} \right], \quad i = 1, \ldots, n, \quad \forall t, \tag{2}\]

where \( M_{t,t+1}(\theta) = \delta U'(C_{t+1}; \gamma)/U'(C_t; \gamma) \) is a parameterized stochastic discount factor (sdf) [see e.g. Hansen, Richard (1987), Hansen, Jagannathan (1991), Bansal, Viswanathan (1993), Cochrane (2001)]. This pricing formula is assumed to be valid also for the other assets, whose cash-flows are written on \( p_{2,t}, \ldots, p_{n,t} \) and whose current prices are not observed. For instance the price at date \( t_0 \) of a European call, written on \( p_1 \), with strike \( K \) and residual maturity 1 is:

\[ c_{t_0}(1, K) = E_{t_0} \left[ M_{t_0:t_0+1}(\theta)(p_{1:t_0+1} - K)^+ \right]. \]  
\[ \hat{c}_{t_0}(1, K) = \hat{E}_{t_0} \left[ M_{t_0:t_0+1}(\hat{\theta})(p_{1:t_0+1} - K)^+ \right], \]

where \( \hat{\theta} \) is a GMM estimator of \( \theta \) and \( \hat{E}_{t_0} \) is a (functional) estimator of the conditional expectation. For the application to derivative pricing the interest is focused on the conditional moment \( c_{t_0}(1, K) \) of the function \( a = M_{t_0:t_0+1}(p_{1:t_0+1} - K)^+ \), which is the product of the sdf by the derivative payoff. This requires joint estimation of the parameter \( \theta \) and of the conditional distribution.

In practice some derivative prices are observed. For instance we can observe the prices of the short term zero-coupon bond:
\[ B(t, t+1) = E_t \left[ M_{t,t+1}(\theta) \right], \quad t = 1, ..., T, \]  
\[ p_{1:t} = E_t \left[ M_{t,t+1}(\theta) p_{1:t+1} \right], \quad t = 1, ..., T, \]

and for instance the at-the-money call price at date \( t_0 \):
\[ c_{t_0}(1, p_{1:t_0}) = E_{t_0} \left[ M_{t_0:t_0+1}(\theta)(p_{1:t_0+1} - p_{1:t_0})^+ \right]. \]

Therefore the structural parameter \( \theta \) is subject to two types of moment restrictions, which can be satisfied for multiple environments [equations (5) and (6)] or only for a given one [equation (7)].

The aim of this paper is the estimation of conditional moments under conditional moment restrictions. In particular we derive the nonparametric efficiency bound of the conditional moment(s) of interest and explain how to reach this bound. In Section 2 we study the set of moment estimators for both structural parameters and the conditional moment of interest. In practice, especially for derivative pricing, the structural parameters satisfy moment restrictions which can be uniform in the conditioning variable, or conditional on a given value. The two types of restrictions are carefully studied, since they have different consequences concerning the identifiability of structural parameters and the accuracy of the estimator of the conditional moment of interest. We show that there exists an optimal moment method,
called extended method of moments (XMM), for the conditional moment of interest, that is which minimizes its asymptotic variance. This minimal variance defines the so-called (kernel) nonparametric efficiency bound. We derive the explicit expression of the efficiency bound in the general framework. Finally we consider the special cases of limited information, when all constraints are conditional on a given environment, and of full information, when all constraints are uniform with respect to the environment.

By definition the extended method of moments is (kernel) nonparametrically efficient. However it does not provide in general an estimator of the whole conditional distribution. The aim of Section 3 is to consider an information based approach to estimate jointly the structural parameter and the conditional distribution. Then it will be seen that the associated information based estimators of the moments of interest are also (kernel) nonparametrically efficient.

Section 4 is concerned with the application to efficient derivative pricing. We discuss in detail the moment restrictions for this problem and distinguish these constraints depending whether they are uniform with respect to the conditioning value. The approach is applied in Section 5 to a stochastic volatility model. We provide the patterns of the confidence bands on derivative prices according to maturity and strike, and discuss the finite sample properties of the estimated derivative prices and of the structural parameters by Monte-Carlo. The estimators of the structural parameters which correspond to the risk premium on volatility converge at a nonparametric rate, whereas the estimators of the other components of the structural parameter converge at a parametric rate. These different behaviours are consequences of market incompleteness. Section 6 concludes.

2 Extended Method of Moments

In this section we consider the estimation of conditional moments $E_0[a(Y; \theta_0)|X = x]$ under moment restrictions $E_0[g(Y, \theta_0)|X = x] = 0$ from a sample of observations $(x_t, y_t)$, $t = 1, ..., T$, where process $(X_t, Y_t)$ is stationary. In this framework it is important to discuss carefully the set of estimating constraints.

i) Firstly we can be interested in a conditional moment $E_0(a|X_0) = E_0[a(Y; \theta_0)|X = x_0]$ given the constraints $E_0[g(Y; \theta_0)|X = x] = 0, \forall x$. The
moment to be estimated has a conditional interpretation, whereas the parameter $\theta_0$ is defined uniformly in $x$. Equivalently we can consider that we are interested in a conditional moment $E_0(a|x_0)$ under marginal moment restrictions $E_0[g_1(Y; X; \theta_0)] = 0$, where $g_1$ is derived by multiplying function $g(Y; \theta)$ by appropriate instrumental variables. This explains the different rates of convergence for the different parameters, that are a parametric rate for the estimator of $\theta$ (based on marginal moments) and a nonparametric rate for the estimator of the conditional moment $E_0(a|x_0)$. As a consequence the asymptotic accuracy of the estimated moment of interest is not influenced by the estimation of $\theta_0$.

ii) Secondly we can be interested in a conditional moment $E_0(a|x_0) = E_0[a(Y; \theta_0)|X = x_0]$ given the constraints $E_0[g(Y; \theta_0)|X = x_0] = 0$. Both the moment of interest $E_0(a|x_0)$ and the parameter $\theta_0$ have conditional interpretations. The rates of convergence are nonparametric for both parameter $\theta_0$ and conditional moment $E_0(a|x_0)$. The asymptotic accuracy of the estimated conditional moment $E_0(a|x_0)$ will take into account the estimation of $\theta_0$.

These two cases are said with full- and limited information, respectively. In Subsection 2.1 we consider the general framework in which the structural parameter $\theta$ is subject to both types of restrictions, that are uniform or conditional restrictions. We study the set of moment estimators of the conditional moment of interest, look for an optimal one and compute the nonparametric efficiency bound. In Subsection 2.2 the result is applied to the pure limiting cases of full and limited information, respectively.

## 2.1 General framework

Let us consider a general framework with both uniform and conditional constraints:

\begin{align*}
E [g(Y; \theta) | X = x] &= 0, \forall x, \\
E [\tilde{g}(Y; \theta) | X = x_0] &= 0,
\end{align*}

(8)

where $\theta$ is an unknown structural parameter with dimension $p$. As usual in the GMM approach, we assume in a first step that the uniform restrictions have been replaced by a set of marginal restrictions, by introducing a finite number of appropriate instrumental variables. Then in a second step we discuss the choice of the instruments.
2.1.1 Efficiency bound for given instruments

i) Identification condition

Let us introduce instruments \( Z = H(X) \) and let function \( g_1 \) define the corresponding marginal restrictions: \( E_0[Z \cdot g(Y; \theta_0)] = E_0[g_1(Y, X; \theta_0)] = 0 \). Therefore structural parameter \( \theta \) satisfies both marginal and conditional restrictions:

\[
E_0[g_1(Y, X; \theta_0)] = 0, \quad E_0[g_2(Y; \theta_0) \mid X = x_0] = 0,
\]

where \( g_2 = (\tilde{g}', g')' \) is obtained by gathering all conditional restrictions for environment \( x_0 \). Intuitively there exist different situations concerning the identifiability of parameter \( \theta \).

i) If \( \theta \) is identifiable from the marginal restrictions only, the conditional ones \( E_0[g_2(Y; \theta_0) \mid X = x_0] = 0 \) provide a negligible additional information, and the efficient estimator of \( \theta \) will converge at a parametric rate.

ii) If \( \theta \) is not identifiable from the marginal restrictions only, but is identifiable from both types of restrictions, we can expect different parametric, or nonparametric rates of convergence according to the function (component) of parameter \( \theta \) which is considered. This will be the general case. In this situation it is important to introduce \( g \) within the components of \( g_2 \). Indeed the standard instruments introduced in \( g_1 \) are smoothing too much the associated conditional moment restrictions based on \( g \) and erase the information on the parameters difficult to identify.

More precisely, the identification assumptions are the following.

**Assumption A.1:** Parameter \( \theta \) is globally identifiable from marginal and conditional moment restrictions, that is the application:

\[
\theta \rightarrow \left( E_0[g_1(Y, X; \theta)]', E_0[g_2(Y; \theta) \mid X = x_0]' \right)' \quad \text{is one-to-one.}
\]

**Assumption A.2:** Parameter \( \theta \) is locally identifiable from marginal and conditional moment restrictions, that is the matrix:

\[
\begin{pmatrix}
E_0 \left[ \frac{\partial g_1}{\partial \theta} (Y, X; \theta_0) \right]
\frac{\partial g_2}{\partial \theta} (Y; \theta_0) \mid X = x_0
\end{pmatrix}
\]

has full column rank.
The above rank condition implies the order condition $K_1 + K_2 \geq p$, where $K_1$ [resp. $K_2$] denotes the number of marginal restrictions (resp. conditional restrictions). If matrix $E_0 \left[ \partial g_1 / \partial \theta' (Y, X; \theta_0) \right]$ has full column rank, the parameter $\theta$ is locally identifiable from the marginal restrictions only.

The parameters of interest are the structural parameter $\theta_0$ and the conditional moment $\beta_0 = E_0 [a(Y; \theta_0) | X = x_0]$. Let us denote by $L$ the dimension of $a$. These parameters can be written in an extended vector of parameters $\theta^* = (\theta', \beta')$ [see e.g. Back, Brown (1992)]. The true value of $\theta^*$ satisfies the extended set of moment restrictions:

$$
\begin{pmatrix}
E_0 [g_1 (Y, X; \theta_0)] \\
E_0 [g_2 (Y; \theta_0) | X = x_0] \\
E_0 [a (Y; \theta_0) - \beta_0 | X = x_0]
\end{pmatrix} = 0.
$$

Since the dimension of $\beta$ is equal to the number of moments of interest, that is the dimension of $a$, the extended parameter $\theta^*$ is also globally or locally identified under Assumptions A.1, A.2.

ii) Moment estimator

We will now consider moment estimators for $\theta^*$ based on the approximated moment restrictions:

$$
\begin{pmatrix}
\hat{E} [g_1 (Y, X; \theta)] \\
\hat{E} [g_2 (Y; \theta_0) | X = x_0] \\
\hat{E} [a (Y; \theta) - \beta_0 | X = x_0]
\end{pmatrix} \approx 0,
$$

where $\hat{E}$ (resp. $\tilde{E}$) is a sample average (resp. a kernel estimator of the conditional moment). More precisely let us introduce a kernel estimator of the conditional density $f_0(y | x_0)$. For expository purpose we assume that the processes $X_t$ and $Y_t$ have identical dimension $d$, say, which is the case in applications to derivative pricing. The kernel density estimator is defined by:

$$
\hat{f}(y | x_0) = \frac{1}{h_T^d} \sum_{t=1}^T K \left( \frac{y_t - y}{h_T} \right) K \left( \frac{x_t - x_0}{h_T} \right) / \sum_{t=1}^T K \left( \frac{x_t - x_0}{h_T} \right),
$$

(9)
where $K$ is the $d$-dimensional kernel and $h_T$ the bandwidth. The kernel $K$ is a non-negative symmetric function satisfying:

$$\int_{\mathbb{R}^d} K(u)du = 1, \quad u^2 = \int_{\mathbb{R}^d} K^2(u)du < \infty.$$  

The kernel density estimator can be used to approach a conditional moment $E_0(g_2|x_0) = E_0[g_2(Y; \theta)|X = x_0]$ by:

$$\tilde{E}(g_2|x_0) = \int g_2(y; \theta)\hat{f}(y|x_0)dy \approx \sum_{t=1}^T g_2(y_t; \theta)K\left(\frac{x_t - x_0}{h_T}\right) / \sum_{t=1}^T K\left(\frac{x_t - x_0}{h_T}\right).$$

Under standard regularity conditions including the bandwidth conditions: $Th_T^d \to \infty, (Th_T^d)^{1/2} h_T^2 \to 0$ as $T \to \infty$, the estimator $\tilde{E}(g_2|x_0)$ is consistent and asymptotically normal:

$$\sqrt{Th_T^d} \left( \tilde{E}(g_2|x_0) - E_0(g_2|x_0) \right) \overset{d}{\to} N(0, w^2V_0(g_2|x_0) / f_X(x_0)),
$$

where $f_X$ is the marginal density of process $X_t$. In particular the different estimated moments have different rates of convergence, that are $\sqrt{T}$ for $\tilde{E}$, $\sqrt{Th_T^d}$ for $E$.

**Definition 1:** A (kernel) moment estimator $\hat{\theta} = \left(\hat{\theta}', \hat{\beta}'\right)'$ of parameter $\theta^*$ is defined by:

$$\hat{\theta}^*(\Omega) = \arg \min_{\theta^* = (\theta', \beta')'} \left( \sqrt{T} \tilde{E}[g_1(Y, X; \theta)]', \sqrt{Th_T^d} \tilde{E}[g_2(Y; \theta)|x_0]', \sqrt{Th_T^d} \tilde{E}[a(Y; \theta) - \beta|x_0]'ight)\Omega\left( \sqrt{T} \tilde{E}[g_1(Y, X; \theta)]', \sqrt{Th_T^d} \tilde{E}[g_2(Y; \theta)|x_0]', \sqrt{Th_T^d} \tilde{E}[a(Y; \theta) - \beta|x_0]'ight)'\right),
$$

where $\Omega$ is a weighting matrix.

The associated (kernel) moment estimator of parameter $\beta$ is consistent, converges at a nonparametric rate $\sqrt{Th_T^d}$, and is asymptotically normal with a variance-covariance matrix $w^2V_Z(x_0|\Omega)$ depending on the weighting matrix $\Omega$.

**iii) Semi-parametric efficiency bound**

**Definition 2:** The (kernel) semi-parametric efficiency bound $B_Z(x_0, a)$ for
\[ \beta_0 = E_0(a|x_0) \] and given instruments \( Z \) is the minimal asymptotic variance \( V_Z(\Omega) \) corresponding to the optimal choice of \( \Omega \).

The main result of this subsection is that the semi-parametric efficiency bound for \( \beta_0 \) depends on the instrument choice \( Z \) only through the local identification content of the corresponding marginal restrictions:

\[ g_1(Y, X, \theta_0) = Z \cdot g(Y, \theta_0). \]

More precisely, what really matters is the null space of the matrix \( E_0 \left[ \frac{\partial g_1(Y, X; \theta_0)}{\partial \theta} \right] \).

If \( s_Z \) denotes the rank of this matrix, its null space is characterized by a \( p \times (p - s_Z) \) matrix \( R_Z \) whose columns generate the null space:

\[ E_0 \left[ \frac{\partial g_1(Y, X; \theta_0)}{\partial \theta} \right] R_Z = 0. \]

Moreover let us denote by \( \tilde{R} \) a \( p \times s_Z \) matrix such that:

\[ \tilde{R} E_0 \left[ \frac{\partial g_1(Y, X; \theta_0)}{\partial \theta} \right] V^{-1} E_0 \left[ \frac{\partial g_1(Y, X; \theta_0)}{\partial \theta} \right] \tilde{R} = Id_{s_Z}, \]

where:

\[ V = \lim_{T \to \infty} V_0 \left[ \frac{1}{\sqrt{T}} \sum_{t=1}^{T} g_1(Y_t, X_t; \theta_0) \right]. \]

Then, the \((p, p)\) matrix \( R_1 = \left( \tilde{R}, R_Z \right) \) is non singular and allows to define a new parameterization:

\[ \eta = R_1^{-1} \theta = \left( \eta_1', \eta_2' \right)'. \]

Component \( \eta_1 \) represents the \( s_Z \) functions of structural parameters \( \theta \) which are identified from the marginal restrictions while \( \eta_2 \) corresponds to the directions for which the marginal restrictions are not informative:

\[ E_0 \left[ \frac{\partial g_1(Y, X; \theta_0)}{\partial \eta_2} \right] = E_0 \left[ \frac{\partial g_1(Y, X; \theta_0)}{\partial \theta} \right] R_Z = 0. \]

Then, the intuition of the main result below is the following: as far as the semi-parametric efficiency bound for \( \beta_0 \) is concerned, parameters \( \eta_1 \) can be
considered as known without estimation error, since they are actually estimated with a parametric rate of convergence, which is infinitely faster than the non-parametric rate of convergence for estimation of $\beta_0$. This is the reason why the efficiency bound for $\beta_0$ depends on the instrument $Z$ only through the information matrix $I_{0,Z}$:

\[
I_{0,Z} = f_X(x_0) \left( \begin{array}{cc} E_0 \left( \frac{\partial a}{\partial \eta_2} \right) & 0 \\ E_0 \left( \frac{\partial a}{\partial \eta_2} \right) & -\text{Id}_L \end{array} \right) \cdot \left( \begin{array}{cc} V_0(g_2) & \text{Cov}_0(g_2, a) \\ \text{Cov}_0(a, g_2) & V_0(a) \end{array} \right)^{-1} \left( \begin{array}{c} E_0 \left( \frac{\partial a}{\partial \eta_2} \right) \\ E_0 \left( \frac{\partial a}{\partial \eta_2} \right) \end{array} \right) - \text{Id}_L,
\]

where all moments are conditional on $X = x_0$. Note that $I_{0,Z}^{-1}$ is similar to a standard GMM efficiency bound for estimation of parameters $(\eta_2', \beta')$ from moment restrictions based on functions $(g_2', a' - \beta)'$, but, by contrast with the standard setting [Hansen (1982), Back, Brown (1992)], both true unknown values of parameters and restrictions are defined conditional on the given value $x_0$ of $X$.

**Proposition 1**: Let instruments $Z$ satisfying Assumptions A.1 and A.2 be given and the associated information matrix $I_{0,Z}$ be defined by (10). Then, the (kernel) semi-parametric efficiency bound $B_Z(x_0, a)$ for conditional moment $\beta_0 = E_0(a|x_0)$ is the lower diagonal $L \times L$ block of matrix $I_{0,Z}^{-1}$, that is:

\[
B_Z(x_0, a) = \frac{1}{f_X(x_0)} \left\{ V_0 a - \text{Cov}_0(a, g)(V_0g)^{-1}\text{Cov}_0(g, a) \\
+ \left[ E_0 \left( \frac{\partial a}{\partial \theta} \right) R_Z - \text{Cov}_0(a, g)(V_0g)^{-1}E_0 \left( \frac{\partial a}{\partial \theta} \right) R_Z \right] \\
\left[ R_Z'E_0 \left( \frac{\partial a'}{\partial \theta} \right) (V_0g)^{-1}E_0 \left( \frac{\partial a'}{\partial \theta} \right) R_Z \right]^{-1} \\
- \left[ R_Z'E_0 \left( \frac{\partial a'}{\partial \theta} \right) - R_Z'E_0 \left( \frac{\partial a'}{\partial \theta} \right) (V_0g)^{-1}\text{Cov}_0(g, a) \right] \right\},
\]

where all moments are conditional on $X = x_0$ and evaluated at the true parameter value $\theta_0$.

**Proof**: See Appendix 1.  

The matrix $R_Z$ is not unique, but only defined up to a post-multiplication by a $(p - s_Z) \times (p - s_Z)$ non-singular matrix. The above semi-parametric
iv) Interpretation in terms of weak instruments

The problem considered above is related to the use of weak instruments. More precisely the uniform moment restrictions correspond to instruments satisfying the standard conditions, and usually called strong instruments in the literature. The moment restrictions corresponding to a given value of the conditioning variable can be approximately written as:

\[ E_0 \left[ g_2(Y; \theta_0) \mid X = x_0 \right] \simeq E_0 \left[ \frac{1}{f_X(x_0)h_T} K \left( \frac{X - x_0}{h_T} \right) g_2(Y; \theta_0) \right]. \]

Thus they correspond to a "marginal" moment restriction constructed from the instrument \( K \left( \frac{X - x_0}{h_T} \right) / h_T f_X(x_0) \). This instrument admits a local interpretation which explains the different rate of convergence when this "weak" instrument is used. Despite this interpretation, the problem considered above is not a special case of the literature on weak instruments [see e.g. Stock, Wright (2000)]. For instance the functions of the parameters which are weakly [resp. strongly] identified are not known a priori, and the asymptotic properties, especially the rates of convergence, of the associated GMM estimator differ from the other ones obtained in the other types of applications which have been considered.

2.1.2 Nonparametric efficiency bound

i) Optimal instruments

The main lesson of the previous subsection is that the instrument \( Z \) only matters through the null space of \( J_Z = E_0 \left[ \partial g_1(Y, X; \theta_0) / \partial \theta \right] \). Larger this null space, larger is the vector \( \eta_2 \) of structural parameters non-identified from marginal restrictions, which must be estimated at a non-parametric rate jointly with \( \beta \), leading to the asymptotic joint covariance matrix \( I_{0,Z} \). Therefore, if \( Z \) and \( W \) are two alternative sets of instruments such that the null space of \( J_Z^T \) is included in the null space of \( J_W^T \), the semi-parametric efficiency bound \( B_Z(x_0, a) \) cannot be larger than \( B_W(x_0, a) \).

It turns out that there are many ways to choose instruments \( Z \) in order to get a minimal null set for \( J_Z^T \). Let us define the subspace \( N_0 \) of vectors \( v \)
of $\mathbb{R}^p$ such that:

$$E_0 \left[ \frac{\partial g}{\partial \theta} (Y; \theta_0) \mid X = x \right] v = 0, \tag{11}$$

almost surely for the marginal distribution $P^X$ of $X$.

Vectors in $N_0$ correspond to linear combinations of parameters $\theta$ that cannot be identified from uniform restrictions. Subspace $N_0$ is included in the null space of $J_{Z1}^Z$ for any choice of the instruments $Z$. Therefore, this null space will be minimal as soon as it coincides with $N_0$. Let us consider in particular:

$$Z = E_0 \left( \frac{\partial g'(Y; \theta_0)}{\partial \theta} \mid X \right) W(X), \tag{12}$$

where $W(X)$ is ($P^X$-almost surely) a positive definite matrix. Then, for $v$ in the null space of $J_{Z1}^Z$, we have:

$$E_0 \left[ E_0 \left( \frac{\partial g'}{\partial \theta} (Y; \theta_0) \mid X \right) W(X) E_0 \left( \frac{\partial g}{\partial \theta} (Y; \theta_0) \mid X \right) v \right] = 0,$$

or:

$$v' E_0 \left( \frac{\partial g'}{\partial \theta} (Y; \theta_0) \mid X \right) W(X) E_0 \left( \frac{\partial g}{\partial \theta} (Y; \theta_0) \mid X \right) v = 0, \quad P^X\text{-almost surely},$$

or:

$$E_0 \left( \frac{\partial g}{\partial \theta} (Y; \theta_0) \mid X \right) v = 0, \quad P^X\text{-almost surely},$$

that is $v$ belongs to $N_0$. Therefore, the choice (12) of instruments $Z$ provides the minimal null set $J_{Z1}^Z$ and is optimal whenever it fulfills the identification Assumptions A1 and A2. Moreover, for this special choice of instruments, Assumption A2 is clearly tantamount to the following natural identification assumption:

**Assumption A.2**: The structural parameter $\theta$ is locally identifiable from the conditional restrictions, that is $v = 0$ is the only vector which fulfills jointly:

(i) the uniform restrictions: $E_0 \left[ \frac{\partial g}{\partial \theta} (Y; \theta_0) \mid X = x \right] v = 0, \quad P^X\text{-almost surely},$
(ii) the conditional restrictions: \( E_0 \left[ \frac{\partial g^2}{\partial \theta} (Y; \theta_0) \mid X = x_0 \right] v = 0, \) for the given value \( x_0 \) of \( X. \)

Thus, we have shown:

**Lemma 1:** Under Assumptions A.1 and A.2* any instrument \( Z = E_0 \left( \frac{\partial g'}{\partial \theta} \mid X \right) W(X), \) where \( W(X) \) is a positive definite matrix, satisfies Assumption A.2 and is an optimal instrument for \( \beta_0 = E_0(a \mid x_0). \)

Since we focus on nonparametric estimation of \( \beta_0, \) the set of optimal instruments is larger than the standard one derived by Hansen (1982) and Chamberlain (1987) for efficient estimation of the structural parameters \( \theta. \) While in the standard framework \( W(X) = [\text{Var}_0(g(Y, \theta_0) \mid X)]^{-1} \) is the efficient weighting of the conditionally heteroskedastic moment conditions, any choice of a positive definite matrix \( W(X) \) is valid when \( \beta \) is the parameter of interest. Moreover, the optimality result given in Lemma 1 is more general than the standard one, since it does not require full (parametric) identification of \( \theta. \)

**ii) The identification assumption**

Another expression of Assumption A2* can be derived by considering a \( p \times (p - s) \) matrix \( R \) whose columns constitute a basis of the space \( N_0 \) defined in (11). Indeed any vector \( v \) satisfying Assumption A.2* i) can be written as \( v = Rc \) for some \( (p - s) \)-dimensional vector \( c. \) Then, Assumption A.2* ii) becomes:

\[
E_0 \left[ \frac{\partial g^2}{\partial \theta} (Y; \theta_0) \mid X = x_0 \right] R c = 0 \implies c = 0,
\]

that is \( E_0 \left[ \frac{\partial g_2(Y; \theta_0)}{\partial \theta} \mid X = x_0 \right] R \) is full column rank. Thus, Assumption A.2* can be rewritten as:

**Assumption A.2*: The matrix:

\[
E_0 \left[ \frac{\partial g^2}{\partial \theta} (Y; \theta_0) \mid X = x_0 \right] R
\]

is full column rank, for any \( p \times (p - s) \) matrix \( R \) whose columns generate the space \( N_0 \) of vectors \( v \in \mathbb{R}^p \) such that \( E_0 \left[ \frac{\partial g(Y; \theta_0)}{\partial \theta} \mid X = x \right] v = 0, P^X\text{-almost surely.} \)
iii) Kernel nonparametric efficiency bound

Let us now derive the nonparametric efficiency bound. By the above results, matrix $R$ corresponds to matrix $R_Z$ introduced in the previous section for optimal instrument $Z$ in (12). A new parameterization:

$$
\eta = R_1^{-1} \theta = \left( \eta_1', \eta_2' \right)'
$$

can be defined as above with $R_1 = \left( \tilde{R}, R \right)$, where matrix $\tilde{R}$ completes the basis of $R$. Component $\eta_1$ represents the maximal set of structural parameters that can be identified from uniform restrictions only. Then the information matrix $I_0$ corresponding to parameters $(\eta_2', \beta')$ is defined from (10) by:

$$
I_0 = \frac{\partial}{\partial \theta} \left( \begin{array}{c}
E_0 \left( \frac{\partial g}{\partial \theta} \right) R

E_0 \left( \frac{\partial a}{\partial \theta} \right) R
\end{array} \right)
\left( \begin{array}{cc}
V_0 \left( g_2 \right) & Cov_0 \left( g_2, a \right)

Cov_0 \left( a, g_2 \right) & V_0 \left( a \right)
\end{array} \right)^{-1}
\left( \begin{array}{c}
E_0 \left( \frac{\partial g}{\partial \theta} \right) R

E_0 \left( \frac{\partial a}{\partial \theta} \right) R
\end{array} \right).
$$

The main result of this section is a direct consequence of Proposition 1.

**Proposition 2**: Let Assumptions A.1 and A.2* be satisfied. Then the (kernel) nonparametric efficiency bound $a \rightarrow B(x_0, a)$ for conditional moment $E_0(a|x_0)$ is the lower diagonal $L \times L$ block of matrix $I_0^{-1}$, that is:

$$
B(x_0, a) = \frac{1}{f_X(x_0)} \left\{ V_0a - Cov_0(a, g)(V_0g)^{-1}Cov_0(g, a)

+ \left[ E_0 \left( \frac{\partial a}{\partial \theta} \right) R - Cov_0(a, g)(V_0g)^{-1}E_0 \left( \frac{\partial g}{\partial \theta} \right) R \right]

\left[ \tilde{R}' E_0 \left( \frac{\partial g}{\partial \theta} \right) (V_0g)^{-1}E_0 \left( \frac{\partial a}{\partial \theta} \right) R \right]^{-1}

\left[ \tilde{R}' E_0 \left( \frac{\partial a}{\partial \theta} \right) - \tilde{R}' E_0 \left( \frac{\partial g}{\partial \theta} \right) (V_0g)^{-1}Cov_0(g, a) \right]\right\}, \forall a,
$$

where all moments are conditional on $X = x_0$ and evaluated at the true parameter $\theta_0$.

The efficiency bound of Proposition 2 is not modified by post-multiplication of the matrix $R$ by a $(p - s) \times (p - s)$ non-singular matrix.
2.2 Special cases

Proposition 2 can be applied to the full and limited information cases, respectively.

2.2.1 Full information identifiability

When the structural parameter $\theta$ is full information identifiable, the column space of matrix $R$ in Proposition 2 is zero, and we get the Corollary below.

**Corollary 1:** The full information (kernel) nonparametric efficiency bound is:

$$B(x_0, a) = \frac{1}{f_X(x_0)} \left\{ V_0(a|x_0) - \text{Cov}_0(a, g_2|x_0)V_0(g_2|x_0)^{-1}\text{Cov}_0(g_2, a|x_0) \right\}.$$

This result is easily understood when all moment restrictions $E_0[g(Y; \theta_0)|X = x] = 0$ are uniform and $\theta$ is full information identifiable. Since $\theta$ can be estimated at a parametric rate using the marginal moment restrictions, it can be assumed known for the computation of the bound. This explains why the second term of the decomposition of the efficiency bound involving derivatives with respect to $\theta$ vanishes. The same reasoning applies when $\theta$ is full information identifiable and satisfies both uniform and conditional restrictions, since the additional conditional restrictions are not informative for the estimation of $\theta$. Note however that they are informative for the estimation of the moment of interest $\beta_0 = E_0(a|x)$ [indeed the nonparametric efficiency bound in Corollary 1 involves the whole set of constraints $g_2 = (\hat{g}', g')$].

Finally, note that the moment of interest is also equal to:

$$E_0(a|x_0) = E_0[a(Y; \theta_0) - \text{Cov}_0(a, g_2|x_0)V_0(g_2|x_0)^{-1}g_2(Y; \theta_0)|x_0].$$

The bound is nothing but the variance-covariance matrix of the residual term in the affine regression of $a$ on $g_2$. A similar interpretation has already been put forward by Back and Brown (1993) in an unconditional setting and extended to a conditional framework by Bonnal and Renault (2004).
2.2.2 Limited information

Let us now assume that all moment restrictions are conditional on the value \( X = x_0 \):

\[
E \left[ \bar{g}(Y; \theta_0) | X = x_0 \right] = 0.
\]

**Corollary 2**: The limited information (kernel) nonparametric efficiency bound is given by:

\[
B(x_0, a) = \frac{1}{f_X(x_0)} \left\{ V_0 a - \text{Cov}_0(a, \tilde{g})(V_0 \tilde{g})^{-1}\text{Cov}_0(\tilde{g}, a) \right. \\
+ \left[ E_0 \left( \frac{\partial a}{\partial \theta} \right) - \text{Cov}_0(a, \tilde{g})(V_0 \tilde{g})^{-1}E_0 \left( \frac{\partial \tilde{g}}{\partial \theta} \right) \right] \\
\left. \left[ E_0 \left( \frac{\partial \tilde{g}}{\partial \theta} \right) (V_0 \tilde{g})^{-1}E_0 \left( \frac{\partial \tilde{g}}{\partial \theta} \right) \right]^{-1} \right. \\
\left. \left[ E_0 \left( \frac{\partial \tilde{g}}{\partial \theta} \right) - E_0 \left( \frac{\partial \tilde{g}}{\partial \theta} \right) (V_0 \tilde{g})^{-1}\text{Cov}_0(\tilde{g}, a) \right] \right\},
\]

where all moments are conditional on \( X = x_0 \) and evaluated at \( \theta_0 \).

This is the same formula as in Proposition 2 with \( g_2 = \tilde{g} \) and \( R = I_d \), since no direction of \( \theta \) is full-information identifiable.

3 Information based estimator

The estimation of optimal instruments and the derivation of the associated optimal weighting matrix in a moment method may be difficult to implement in practice and provide rather erratic results in finite sample [see e.g. Altonji, Segal (1996), Hansen, Heaton, Yaron (1996)]. It has been proposed in the literature (see the Introduction) to derive the optimal moment estimator in a single step by optimizing with respect to both the structural parameter and the conditional pdf an appropriate measure of discrepancy between the distribution and the unconstrained kernel density subject to the moment restrictions. The discrepancy measure is chosen among the Cressie-Read family of divergences [Cressie, Read (1984)], leading to the so-called empirical likelihood, chi-square or Kullback-Leibler information based (KLIC) approach. The whole existing literature assumes the full information identifiability of
parameter \( \theta \). In this section we develop an approach for the mixed framework by combining in an appropriate way chi-square and KLIC measures. The aim of this approach is to get an estimator of the conditional pdf, which satisfies the unit mass and non-negativity restrictions\(^2\), while keeping the estimator tractable.

In the first subsection, we note that the XMM approach features a lack of coherency, and does not provide an appropriate approximation of the conditional density. The information based estimator is introduced in Section 3.2 and its (kernel) nonparametric efficiency is proved. Finally Section 3.3 considers the pure cases of full and limited information.

### 3.1 A lack of coherency of XMM

It is well-known that a GMM approach can feature a lack of coherency, when the conditional moments of interest are multiple. More precisely, it is expected that an estimation approach for \( E_0(a|x_0) = E[a(Y; \theta_0)|X = x_0] \) provides an estimator of the type:

\[
\hat{E}(a|x_0) = \int a(y; \tilde{\theta}) \tilde{f}(y|x_0) dy,
\]

where \( \tilde{\theta} \) is an estimator of \( \theta \) and \( \tilde{f} \) is an estimator of the conditional density. The XMM approach does not satisfy this requirement.

i) For instance in the full-information case with full information identifiable parameter, the XMM estimator of the moment of interest coincides with the estimator of the moment of the residual:

\[
E_0 \left[ a(Y; \theta_0) - \text{Cov}_0 (a, g|x_0) V_0 (g|x_0)^{-1} g(Y; \theta_0) \mid x_0 \right],
\]

which can be written as:

\[
\int a(y; \theta_0) \tilde{f}(g|x_0) \left[ 1 - g(y; \theta_0) V_0 (g|x_0)^{-1} E_0 (g|x_0) \right] dy.
\]

This is an integral expression, with respect to a measure which does not depend on \( a \), satisfies the unit mass restriction, but is not necessarily positive.

\(^2\)These conditions are required for derivative pricing where the conditional (risk neutral) pdf is interpreted as a state price density. It avoids misleading arbitrage opportunities in estimated option prices.
Moreover in the general mixed framework such an integral representation can even not exist, since the XMM estimator of $\theta$ depends on the moment of interest $a$.

Therefore, it is important to introduce an estimation method, which is both coherent and (kernel) nonparametrically efficient.

### 3.2 Information based estimator

The (unconstrained) kernel estimator $\hat{f}(y|x)$ is a consistent estimator of the conditional pdf. However it is not nonparametrically efficient, since it does not take into account the parameterized moment restrictions. The kernel density estimator can be improved by looking for the pdf which is the closest to $\hat{f}(y|x)$ and satisfies the moment restrictions.

In this section we consider the joint estimator defined by:

$$
\left( \hat{f}_0(.|x_0), \hat{f}_0(.|x_1), ..., \hat{f}_0(.|x_T), \hat{\theta} \right)
$$

$$
= \arg \min_{f_1, f_2, ..., f_T, \theta} \frac{1}{T} \sum_{t=1}^{T} \int \frac{\left[ \hat{f}(y|x_t) - f^t(y) \right]^2}{\hat{f}(y|x_t)} dy + h_T^2 \int \log \left[ f^0(y)/\hat{f}(y|x_0) \right] f^0(y) dy,
$$

s.t. \quad \int f^t(y) dy = 1, \quad t = 1, ..., T,

\int f^0(y) dy = 1,

\int g(y; \theta) f^t(y) dy = 0, \quad t = 1, ..., T,

\int g_2(y; \theta) f^0(y) dy = 0.

The objective function includes two components: a chi-square distance is used for the optimization with respect to the conditional distributions associated with the sample values of the conditioning variable, whereas an information criterion is used for the conditioning value $x_0$ corresponding to the conditional moment of interest. Moreover two types of constraints are introduced: the uniform restrictions are written for all observations $x_1, ..., x_T$, whereas the conditional restrictions are written for $x_0$ only. The chi-square components allow for a simple computation of solutions $f^1(\theta), ..., f^T(\theta)$ for a given $\theta$ without ensuring positivity. Therefore the objective function is easily concentrated with respect to $f^1, ..., f^T$. Then the information criterion will allow a solution $\hat{f}_0(.|x_0)$ satisfying the unit mass and positivity restrictions.

\[3\text{See e.g. Kitamura-Stutzer (1997) in an unconditional framework.}\]
In particular, the computation of the estimator only involves the optimization of a concentrated criterion with respect to parameter $\theta$ and a Lagrange multiplier of dimension $\dim(g_2)$ [see Appendix 2 i) for the concentration of the objective function].

Then the information based estimator of the conditional moment is defined by:

$$\hat{E}(a|x_0) = \int a(y; \hat{\theta}) \hat{f}_0(y|x_0) dy.$$ 

The (kernel) nonparametric efficiency of the information based estimator of $f_0(y|x_0)$ is proved in Appendix 2.

**Proposition 3** The estimator $\hat{E}(a|x_0)$ is consistent, converges at rate $\sqrt{Th_T}$, is asymptotically normal and (kernel) nonparametrically efficient:

$$\frac{\sqrt{Th_T}}{w}(\hat{E}(a|x_0) - E_0(a|x_0)) \xrightarrow{d} N(0, B(x_0, a)),$$

for any $a$.

### 3.3 Special cases

#### 3.3.1 Limited information

When the moment restrictions are:

$$E_0[g(Y; \theta_0)|X = x_0] = \int g(y; \theta_0) f_0(y|x_0) dy = 0,$$

the optimization problem becomes:

$$\left( \hat{f}_0(\cdot|x_0), \hat{\theta} \right) = \arg \min_{f, \theta} \int \log \left[ f(y)/\hat{f}(y|x_0) \right] f(y) dy$$

s.t. $\int f(y) dy = 1, \int f(y) g(y; \theta) dy = 0.$

The associated estimator $\hat{E}(a|x_0) = \int a(Y; \hat{\theta}) \hat{f}_0(y|x_0) dy$ is (kernel) nonparametrically efficient. Its asymptotic variance is given by the expression of $B(x_0, a)$ in Corollary 2.
3.3.2 Full information

In the full information case a (kernel) nonparametrically efficient estimator can be defined by optimizing the mixed chi-square/information criterion with respect to both \( \theta \) and the conditional distribution [see Section 3.2]. Our approach extends results derived in the literature in the special case of pure uniform restrictions and i.i.d. observations. For instance Bonnal and Renault (2004) derive a result similar to Proposition 3, but without imposing positivity of the estimated conditional distribution. Kitamura, Tripathi, Ahn (2001) and Smith (2004) focus on estimation and inference about structural parameter \( \theta \) in a smooth empirical likelihood and GEL setting, respectively\(^4\).

In the full information case, a (kernel) efficient estimator of the moment of interest can also be derived in a two step approach. Indeed the structural parameter \( \theta \) can be estimated consistently (and efficiently) by means of the uniform restrictions only. This allows to separate the estimation of \( \theta \) and the estimation of the conditional pdf of interest \( f(y|x_0) \). A two step estimator is defined by:

\[
\hat{E}(a|x_0) = \int a(y; \hat{\theta}) \hat{f}_0(y|x_0) dy,
\]

where:

\[
\hat{f}_0(.|x_0) = \arg \min \int \log[f(y)/\hat{f}(y|x_0)] f(y) dy,
\]

s.t. \( \int f(y) dy = 1, \int f(y) g_2(y; \hat{\theta}) dy = 0 \),  \hspace{1cm} (14)

and \( \hat{\theta} \) is any estimator of \( \theta \) converging at a parametric rate. This estimator can be a consistent (but possibly inefficient) moment estimator, a GMM estimator, or a continuously updated estimator [see Hansen, Heaton, Yaron (1996)]. Insofar as \( \hat{\theta} \) is consistent and root-\( T \) asymptotically normal, \( \hat{E}(a|x_0) \) reaches the (kernel) nonparametric efficiency bound in Corollary 1. By contrast with standard GMM, the two-step procedure does not imply any efficiency loss since the rates of convergence are different in the two steps.

\(^4\)See also Ai-Chen (2003).
4 Derivative pricing

Usually derivative pricing formulas involve two types of parameters characterizing the dynamic of the underlying asset returns and the risk premia, respectively. The parameters can be finite dimensional or functional, leading in practice to parametric or nonparametric pricing methods.

When the markets are complete, the only parameter concerns the dynamics of the underlying asset returns and can be estimated from return data. When the parameter is finite dimensional, it is usually estimated by maximum likelihood. This approach can be extended to functional parameter, leading for instance to indirect spline estimation of the state price density [see e.g. Gourieroux, Monfort (2001)]. Alternatively the estimation of some parameters can be based on derivative data only. For instance, if the Black-Scholes model is well-specified, the volatility can be estimated by an implied volatility computed from an observed option price. However the drift is not identifiable from option prices, that is by a cross-sectional approach.

In the incomplete market framework, the model includes in general both dynamic and risk premia parameters. These parameters can be estimated by an appropriate use of both historical and cross-sectional data. Such approaches have already been considered in the literature for parametric models [see e.g. Garcia, Luger, Renault (2003) for estimation, De Munnik, Schotman (1994), Bams (1998) for specification tests]. Some of the parameters can also be estimated by a pure cross-sectional approach using option data, the typical example being the parametric fit of Black-Scholes implied volatility surfaces. Different nonparametric approaches have also been considered in the literature. They are based for instance on the nonparametric approximation of the implied volatility surface [see e.g. Hutchinson, Lo, Poggio (1994) for using neural networks, and Ait-Sahalia, Lo (1998), who use a kernel approach and deduce a nonparametric estimator of the state price density]. An alternative approach relies on maximum entropy risk neutral densities for given maturity, derived by using both asset and option data [see e.g. Rubinstein (1994), Jackwerth, Rubinstein (1996), Buchen, Kelly (1996), Stutzer (1996), Jondeau, Rockinger (2000)]. In this section, we consider a semi-nonparametric approach, in which the historical parameter is functional and the risk premia parameter is finite dimensional. We explain how to use jointly underlying returns and derivative prices for efficient pricing of other derivatives.
4.1 The estimating constraints

For expository purpose let us consider European calls written on an underlying asset with geometric return $y_t$. We assume that the return series $(Y_t)$ is a Markov process of order one under the historical probability and that the price at $t$ of a European call with moneyness strike $s$ and residual maturity one can be written as:

$$c_t(s) = E_t \left[ m(Y_{t+1}; \theta) (\exp Y_{t+1} - s)^+ \right],$$

where $m(Y_{t+1}; \theta)$ is the stochastic discount factor. The finite dimensional parameter $\theta$ characterizes the risk premia, whereas the historical conditional distribution of $Y_{t+1}$ given $Y_t$ is let unspecified.

Let us now assume observations of a finite number of derivative prices $c_{t_0}(s_k), k = 1, \ldots, K$, at a given date $t_0$ and observations of underlying asset returns for date $t = t_0 - T + 1, \ldots, t_0$. Then the moment restrictions are twofold. Some constraints concern the derivatives and are given by:

$$c_{t_0}(s_k) = E \left[ m(Y_{t+1}; \theta) (\exp Y_{t+1} - s_k)^+ | Y_t = y_{t_0} \right], k = 1, \ldots, K. \quad (16)$$

Other constraints concern the pricing formula for the underlying asset and the riskfree asset. They are:

$$E[m(Y_{t+1}; \theta) | Y_t = y_t] = 1, \forall y_t,$$

$$E[m(Y_{t+1}; \theta) \exp Y_{t+1} | Y_t = y_t] = 1, \forall y_t,$$

assuming for simplicity a deterministic zero risk-free rate.

The second subset of constraints on $\theta$ are uniform with respect to the conditioning value, whereas the conditioning value is fixed in the first subset. The distinction between the two types of moment restrictions is due to the lack of liquidity of some assets. If the asset is highly liquid, its price can be observed at any date leading to uniform conditional moment restrictions (if the number of observation dates is large and the return process stationary with a continuous stationary distribution). If the asset is not very liquid the

\footnote{Since $(p_{t+1} - s p_t)^+ = p_t (\exp y_{t+1} - s)^+$, the call or put written on $p_{t+1}$ can also be written on $\exp y_{t+1}$.}
price is observed for a limited number of dates, for instance for environment \(y_{t_0}\) existing at date \(t_0\) \(^6\). This is the case for derivatives.

Different pricing formulas are derived below depending whether the second subset of moment restrictions is totally taken into account.

### 4.2 Derivative pricing with limited information

Let us assume that the interest is in the price at \(t_0\) of a European call with maturity 1 and strike \(s\). Its price is equal to the conditional moment:

\[
E(a|y_{t_0}) = E[m(Y_{t+1}; \theta)(\exp Y_{t+1} - s)^+|Y_t = y_{t_0}].
\]

Under limited information, the only restrictions \(E(\bar{g}|y_{t_0}),\) which are taken into account, correspond to the same conditioning value. There is a set of \(K + 2\) restrictions:

\[
\begin{align*}
E[m(Y_{t+1}; \theta)(\exp Y_{t+1} - s_k)^+ - c_{t_0}(s_k)|Y_t = y_{t_0}] &= 0, \quad k = 1, \ldots, K, \\
E[m(Y_{t+1}; \theta) - 1|Y_t = y_{t_0}] &= 0, \\
E[m(Y_{t+1}; \theta) \exp Y_{t+1} - 1|Y_t = y_{t_0}] &= 0.
\end{align*}
\] (18)

Then we can apply the estimation approach described in Section 3.3.1. This approach ensures that the estimated risk neutral pdf is nonnegative, which is compatible with the no arbitrage restrictions \(^7\).

Whereas the conditional moment restrictions concern date \(t_0\) and environment \(y_{t_0}\) only, the approach is not a pure cross-sectional approach. Indeed the observations \(y_{t_0-T+1}, \ldots, y_{t_0}\) corresponding to the other dates are used in the estimation approach of the conditional (historical) pdf. In particular the derivative prices will be consistently estimated, if the number of observations

\(^6\)See the discussion in Aït-Sahalia, Lo (1998) for the evolution of the set of liquid options on S&P.

\(^7\)The conditional moments could also be estimated by XMM, but as noted in Section 3.1 this does not ensure a corresponding risk neutral density, and, if the latter exists, its positivity. Thus XMM could create misleading arbitrage opportunities in estimated option prices.
$T$ is large, even if the number of derivatives $K$ is rather small (but larger
than the parameter size) \footnote{In particular the asymptotic theory is very different and more realistic than the theory developed by e.g. Ait-Sahalia, Lo (1998), who assume an infinite number of liquid derivatives at the date of interest.}.

Finally note that the limited information method differs from the ent-
tropy based approaches introduced in the literature by the choice of the
benchmark risk neutral distribution. In our framework this distribution is
$m(y; \theta_0)f_0(y|x_0)$, where $f_0(.|x_0)$ is the historical conditional pdf. In Stutzer
(1996) p1639 the benchmark distribution is the historical distribution itself
(implicitly assuming zero risk premia), a parametric prior such as a Black-
Scholes lognormal distribution is suggested by Rubinstein (1994) and Jackw-
erth, Rubinstein (1996), whereas a uniform distribution has been implicitly
selected in Buchen, Kelly (1996) and Jondeau, Rockinger (2000). Moreover,
maximum entropy methods focus on the state price density for a given matur-
ity, whereas our approach allows to estimate coherently state price densities
at any maturity.

4.3 Derivative pricing with mixed limited- and full in-
formation

Let us now assume that both types of moment restrictions (16) and (17)
are taken into account. Derivative pricing can be improved by considering
jointly the dynamics of the underlying asset prices between $t = t_0 - T + 1$
and $t = t_0$ and the way some prices of European calls depend on the strike
for date $t_0$.

Two cases have to be distinguished according to the full information identi-
fiability of parameter $\theta$ from underlying asset price dynamics.

i) Full information identifiability

If parameter $\theta$ is identifiable from uniform moment restrictions (17), re-
strictions (16) can asymptotically be neglect for the estimation of $\theta$. A GMM
estimator $\hat{\theta}$ of $\theta$ can be computed by using restrictions (17) only and is con-
sistent at a parametric rate. Then we can apply the estimation method
described in Section 3.3.2 with $\hat{f}(.,x_0)$ a kernel estimator of the conditional
pdf given $Y_t = y_{t_0}$ and the set of restrictions (18).
ii) Full information underidentifiability

As seen in Section 2.1, a part of the parameters can be identified from the asset price dynamics (uniform restrictions) and will converge at a parametric rate, whereas the remaining parameters are identified by means of the cross-sectional restriction (16) and converge at a nonparametric rate. The latter are linear combinations of parameters $R' \theta$, where the columns of matrix $R$ span the null space $N_0$ defined in (11), with moment function $g$ corresponding to restrictions (17). In this case the estimation has to be performed with the general criterion introduced in Section 3.2.

When $\theta$ is full information underidentified there exist a multiplicity of values of parameter $\theta$, that is a multiplicity of sdf, such that the no-arbitrage conditions (17) are satisfied. In the incomplete market framework, the choice of a parametric specification for the sdf may be not sufficient to get a unique pricing kernel. In other words, the specification allows for some residual incompleteness and, from a financial point of view, the degree of full information underidentification is equal to the dimension of this residual incompleteness.

4.4 Comparison of the limited and mixed information approaches

Let us first note that both approaches use jointly historical information (by means of the kernel estimate of the conditional pdf and possibly by uniform moment restrictions (17)) and cross sectional information by moment restrictions (16). Moreover they are consistent when $T$ tends to infinity with $K$ fixed, whenever $\theta$ is identifiable from the whole set of uniform and conditional moment restrictions.

When $\theta$ is identifiable from the conditional restrictions at date $t_0$, it is possible to use either the general approach, or the limited information approach. The limited information method is likely to be preferred in practice in a first step. Firstly the asymptotic variance is larger than the variance derived by the general approach, leading to larger prediction intervals for derivative prices, but more secure risk management. Secondly this is the analogue of reporting daily the implied volatilities in the Black-Scholes framework. More precisely let us assume that the pricing model is misspecified and that the stochastic discount factor is $m(y_{t+1}, \theta(y_t))$, in which $\theta$ depends on the lagged value. The limited information method provides the estimate of
\( \theta(y_t) \), whereas the general method provides a kind of average of \( \theta(y_t) \) on all values observed in the past, without the interpretation of an integrated risk premium.

5 Stochastic volatility model

The aim of this section is to illustrate the extended method of moments (XMM), or its information based equivalent, for efficient derivative pricing. In Section 5.1 we describe the data generating process to get the prices of the underlying asset and derivatives. The DGP is a discrete time version of the stochastic volatility model of Heston (1993) and Ball-Roma (1994), with a risk premium introduced in the return equation. In Section 5.2 we describe the semi-parametric model which is used for derivative pricing and discuss the identification of the risk premia parameter. The nonparametric efficiency bounds for limited- and mixed information restrictions are computed in Section 5.3 for the prices of European calls. We discuss how they depend on the strike and on the set of observed derivatives. Finally, the finite sample properties of the estimated option prices and of the estimated structural parameters are analyzed by Monte-Carlo in Section 5.4.

5.1 The design

Let us consider a market with a risk-free asset, with a zero risk-free rate, and a risky asset with geometric return

\[
  r_t = \log \left( \frac{p_t}{p_{t-1}} \right)
\]

such that:

\[
  r_t = \gamma \sigma_t^2 + \sigma_t \varepsilon_t,
\]

(19)

where \( \varepsilon_t \) is a standard Gaussian white noise, \( \sigma_t^2 \) denotes the volatility and \( \gamma \) measures the magnitude of the risk premium in the expected return. The intercept is set to zero because of no-arbitrage restrictions. Indeed for \( \sigma_t = 0 \) the return becomes deterministic and has to coincide with the zero risk-free rate.

The volatility \( \sigma_t^2 \) is stochastic, with a dynamics independent of the shocks \( \varepsilon_t \) on returns. It follows an autoregressive gamma process (ARG), which is the time discretized Cox-Ingersoll-Ross process [see Gouriéroux, Jasiak (2000)]. The transition distribution of the stochastic volatility is char-
acterized by the conditional Laplace transform:

\[
\Psi_t(u) = E \left[ \exp \left( -u \sigma_{t+1}^2 \right) \mid \sigma_t^2 \right] \\
= \exp \left[ -a(u) \sigma_t^2 - b(u) \right],
\]

(20)

where: \( a(u) = \rho u \frac{u}{1+cu} \), \( b(u) = \delta \log(1 + cu) \). The positive parameter \( \rho \) is the first order autocorrelation of the variance process \( (\sigma_t^2) \), parameter \( \delta \geq 0 \) describes its (conditional) over-/under-dispersion, and \( c > 0 \) is a scale parameter. In this model the factors are the return and the volatility:

\[ Y_t = (r_t, \sigma_t^2). \]

(21)

Model (19)-(21) is completed by the parametric specification of the stochastic discount factor for period \((t, t+1)\). The sdf is specified as:

\[
M_{t,t+1} = \exp \left( -\nu_0 - \nu_1 \sigma_{t+1}^2 - \nu_2 \sigma_t^2 - \nu_3 r_{t+1} \right),
\]

(22)

where \( \nu_0, \nu_1, \nu_2, \nu_3 \) are parameters. The exponential affine specification (22) is compatible with the no-arbitrage restrictions and provides simple pricing formulas.

Let us first consider the restrictions implied by no-arbitrage opportunity. They are obtained by writing the pricing formula for both the risk-free asset and the underlying asset. We get:

\[
\begin{align*}
&\begin{bmatrix}
E_t(M_{t,t+1}) = 1, \\
E_t(M_{t,t+1} \exp r_{t+1}) = 1, \\
E_t \exp \left[ -\nu_0 - \nu_1 \sigma_{t+1}^2 - \nu_2 \sigma_t^2 - \nu_3 r_{t+1} \right] = 1, \\
E_t \exp \left[ -\nu_0 - \nu_1 \sigma_{t+1}^2 - \nu_2 \sigma_t^2 - (\nu_3 - 1) r_{t+1} \right] = 1, \\
E_t \exp \left[ -\nu_0 - \left( \nu_1 + \nu_3 \gamma - \frac{\nu_3^2}{2} \right) \sigma_{t+1}^2 + \nu_2 \sigma_t^2 \right] = 1, \\
E_t \exp \left[ -\nu_0 - \left( \nu_1 + (\nu_3 - 1) \gamma - \frac{(\nu_3 - 1)^2}{2} \right) \sigma_{t+1}^2 - \nu_2 \sigma_t^2 \right] = 1, \\
\end{bmatrix}
\end{align*}
\]

(by integrating \( r_{t+1} \) conditional on \( \sigma_{t+1}^2 \))

\[
\begin{align*}
&\begin{bmatrix}
\nu_0 + a \left( \nu_1 + \nu_3 \gamma - \frac{\nu_3^2}{2} \right) \sigma_t^2 + \nu_2 \sigma_t^2 + b \left( \nu_1 + \nu_3 \gamma - \frac{\nu_3^2}{2} \right) = 0, \\
\nu_0 + a \left( \nu_1 + (\nu_3 - 1) \gamma - \frac{(\nu_3 - 1)^2}{2} \right) \sigma_t^2 + \nu_2 \sigma_t^2 + b \left[ \nu_1 + (\nu_3 - 1) \gamma - \frac{(\nu_3 - 1)^2}{2} \right] = 0.
\end{bmatrix}
\end{align*}
\]

(23)
Since the above conditions have to be satisfied for any admissible value of $\sigma_t^2$, we get the following restrictions on the parameters:

$$\begin{cases}
\nu_0 + b \left( \nu_1 + \nu_3 \gamma - \frac{\nu_3^2}{2} \right) = 0, \\
\nu_0 + b \left[ \nu_1 + (\nu_3 - 1) \gamma - \frac{(\nu_3 - 1)^2}{2} \right] = 0, \\
\nu_2 + a \left( \nu_1 + \nu_3 \gamma - \frac{\nu_3^2}{2} \right) = 0, \\
\nu_2 + a \left[ \nu_1 + (\nu_3 - 1) \gamma - \frac{(\nu_3 - 1)^2}{2} \right] = 0.
\end{cases}$$

Since functions $a$ and $b$ are one-to-one, the difference between the first two equations (resp. the last two equations) imply:

$$\nu_1 + (\nu_3 - 1) \gamma - \frac{(\nu_3 - 1)^2}{2} = \nu_1 + \nu_3 \gamma - \frac{\nu_3^2}{2},$$

that is:

$$\nu_3 = \gamma + \frac{1}{2}.$$

From the same pairs of equations we deduce:

$$\begin{align*}
\nu_0 &= -b \left( \nu_1 + \nu_3 \gamma - \frac{\nu_3^2}{2} \right) = -\delta \log \left[ 1 + c \left( \nu_1 + \gamma^2/2 - 1/8 \right) \right], \\
\nu_2 &= -a \left( \nu_1 + \nu_3 \gamma - \frac{\nu_3^2}{2} \right) = -\rho \frac{\nu_1 + \gamma^2/2 - 1/8}{1 + c \left( \nu_1 + \gamma^2/2 - 1/8 \right)}.
\end{align*}$$

(24)

Therefore we get the following proposition.

**Proposition 4 :** The sdf (22) is compatible with the no-arbitrage conditions if and only if:

$$\begin{align*}
\nu_0 &= -\delta \log \left[ 1 + c \left( \nu_1 + \gamma^2/2 - 1/8 \right) \right], \\
\nu_2 &= -\rho \frac{\nu_1 + \gamma^2/2 - 1/8}{1 + c \left( \nu_1 + \gamma^2/2 - 1/8 \right)}, \\
\nu_3 &= \gamma + 1/2.
\end{align*}$$

In particular parameter $\nu_1$ is unrestricted. Thus in this incomplete market framework the risk premium for current stochastic volatility can be fixed arbitrarily, that is the dimension of residual incompleteness is equal to 1. This residual incompleteness is not a consequence of the specific ARG dynamics.
assumed for stochastic volatility, but will be the general case for instance when state variables $Y_t$ follow an affine process. Indeed in this case the specification of a parametric exponential affine sdf generally does not select a unique pricing kernel.

The (standardized) price at $t$ of a European call with moneyness strike $k$ and residual maturity $h$ is given by:

$$c_t(h, k) = \frac{1}{p_t} E_t \left[ M_{t+1} \ldots M_{t+h-1} (p_{t+h} - kp_t)^+ \right]$$

$$= E_t \left( M_{t+1} \ldots M_{t+h-1} \left[ \exp \left( r_{t+1} + \ldots + r_{t+h} \right) - k \right]^+ \right).$$

As usual in the stochastic volatility framework, the option price can be written in terms of Black-Scholes price and integrated volatility

$$\sigma^2_{t+1}(h) = (\sigma^2_{t+1} + \ldots + \sigma^2_{t+h}) / h.$$ We get:

$$c_t(h, k) = E_t BS(h, k, \sigma^2_{t+1}(h)),$$

where $Q$ is the risk neutral probability and $BS(h, k, \sigma^2)$ denotes the Black-Scholes price of a European call with moneyness strike $k$, residual maturity $h$ and constant volatility $\sigma^2$. The derivative price is easily computed by Monte-Carlo since under the risk neutral probability the returns still follow stochastic volatility model (19)-(20) with risk premium parameter $\gamma^* = -1/2$ and ARG volatility parameters$^9$:

$$\rho^* = \frac{\rho}{\left[ 1 + c (\nu_1 + \gamma^2/2 - 1/8) \right]^2}, \quad \delta^* = \delta, \quad c^* = \frac{c}{1 + c (\nu_1 + \gamma^2/2 - 1/8)}.$$  \hspace{1cm} (25)

To illustrate the properties of the stochastic ARG volatility model discussed above, we display in Figures 1 and 2 below a joint simulated path for the return and the volatility, and the pattern of the implied Black-Scholes volatility as function of the moneyness strike, respectively. The simulations are performed for the following set of values for the parameters:

<table>
<thead>
<tr>
<th>$\gamma$</th>
<th>$\rho$</th>
<th>$\delta$</th>
<th>$c$</th>
</tr>
</thead>
<tbody>
<tr>
<td>0.5</td>
<td>0.85</td>
<td>1.266</td>
<td>2.7E-5</td>
</tr>
<tr>
<td>$\nu_0$</td>
<td>$-3.37E-4$</td>
<td>$\nu_1$</td>
<td>$-8.498$</td>
</tr>
</tbody>
</table>

$^9$The proof is available from the authors.
As expected, the return series features volatility clustering, with periods of high return volatility corresponding to large values of the stochastic volatility. The Black-Scholes implied volatility\footnote{We select a residual maturity $h = 1$ for the European call and the relevant information at date $t$ is the volatility $\sigma_t^2$ whose value is set equal to the stationary mean $E\sigma_t^2$.} admits an asymmetric smile, more pronounced for in-the-money values of the strike $k$.

5.2 The observations and the model

In the following sections we assume that the observations are $r_{t_0-T+1}, \ldots, r_{t_0}$, $\sigma_{t_0-T+1}^2, \ldots, \sigma_{t_0}^2$ and some derivative prices at date $t_0$, corresponding to moneyness strikes $s_1 = 1$, $s_2 = 0.98$, $s_3 = 1.02$. The observed prices have been generated by the design of Section 5.1 with the same set of parameter values. We are now interested in an efficient estimation of some option prices.

i) The model

For simplicity we assume that the specified sdf is compatible with the design above:

$$M_{t,t+1}(\theta) = \exp\left(-\nu_0 - \nu_1 \sigma_{t+1}^2 - \nu_2 \sigma_t^2 - \nu_3 r_{t+1}\right),$$

where $\theta = (\nu_0, \nu_1, \nu_2, \nu_3)'$ is an unknown parameter. Moreover the conditional distribution of $Y_t = (r_t, \sigma_t^2)$ given $Y_{t-1}$ is let unspecified.

ii) Full information identifiability

Let us now discuss the identifiability of parameter $\theta$ from the uniform conditional restrictions:

$$\begin{cases} E_t(M_{t,t+1}(\theta)) = 1, \\ E_t(M_{t,t+1}(\theta) \exp r_{t+1}) = 1, \end{cases}$$

assumed valid for any conditioning value $y_t$. From Proposition 4, we see that only three independent functions of parameter $\theta$ can be identified, including parameter $\nu_3$. Therefore in this model the parameter $\theta$ is full information underidentified.

At this step two approaches can be followed:
I. We can consider the stochastic discount factor above without introducing additional restrictions on parameters $\nu_0, \nu_1, \nu_2$. Then the degree of underidentification from asset dynamics is equal to 1. The null space $N_0$ defined in equation (11) has dimension 1, and is spanned by [see Appendix 3]:

$$R = \begin{pmatrix} -\delta \frac{c}{1 + \alpha_1} \\ 1 \\ -\rho \frac{1}{(1 + \alpha_1)^2} \\ 0 \end{pmatrix} = \begin{pmatrix} -3.37E - 5 \\ 1 \\ -0.850 \\ 0 \end{pmatrix}. \quad (26)$$

Component $R^T \theta$ involving parameters $\nu_0, \nu_1, \nu_2$ is full information non-identified. Typically parameters $\nu_0, \nu_1, \nu_2$ can only be identified from the cross-sectional restrictions.

II. Alternatively, we can introduce an identification restriction on the risk premium, for instance $\nu_1 = 0$. Under this restriction $\nu_0, \nu_1, \nu_2$ become full information identifiable from asset price dynamics, and the estimation problem will be greatly simplified. It is interesting to note that this second approach is often followed in the financial literature, at the risk of a mispecification in the identification restriction. Moreover such an approach can have some misleading consequences when considering the confidence interval for derivative prices, which will likely be too narrow.

The first approach will be considered in this paper.

III) Limited information identifiability and residual maturity

An additional identification problem may arise in the limited information framework. Indeed in this case, the conditional moment restrictions are valid only for the conditioning value $y_{t_0}$ observed at time $t_0$, and parameters $\nu_0$ and $\nu_2$ cannot be identified separately by including cross-sectional restrictions from observed prices of derivatives with residual maturity $h = 1$. Only parameters $\nu_{0,t_0} = \nu_0 + \nu_2 \sigma^2_{t_0}$ and $\nu_1$ can be identified from asset dynamics and observed derivative prices. However parameters $\nu_0$ and $\nu_2$ can be identified separately by means of observed prices of derivatives with residual maturity larger than 1.
When the structural parameter is full information underidentified the identification problem can be solved by observing derivative prices. We have considered above European calls with residual maturity 1. Of course the identification can also be obtained with another residual maturity for the option such as \( h = 2, 3, \ldots \). However the derivative prices with large residual maturity are much less informative. Indeed, let us consider the geometric stochastic yield associated with the sdf, that is:

\[
-\frac{1}{h} \log (M_{t,t+1} \cdots M_{t+h+1,t+h}) = \nu_0 + \nu_1 \frac{1}{h} \sum_{k=1}^{h} \sigma^2_{t+k} + \nu_2 \frac{1}{h} \sum_{k=0}^{h-1} \sigma^2_{t+k} + \nu_3 \frac{1}{h} \sum_{k=1}^{h} r_{t+k}.
\]

If the joint process \((\sigma^2_t, r_t)\) is stationary, the geometric stochastic yield tends to the deterministic long run level \( \nu_0 + (\nu_1 + \nu_2) E\sigma^2_t + \nu_3 Er_t \) for \( h \) tending to infinity. Thus this combination of the structural parameters is limited information identifiable from long run derivative prices, but the structural parameters themselves are not.

iv) Link with the literature

Stock, Wright (2000) considered also an application to asset pricing formula, in which the sdf is deduced from the optimisation of an expected CRRA utility function. Thus the sdf is:

\[
M_{t,t+1}(\theta) = \delta (C_{t+1}/C_t)^\gamma,
\]

where \( C_t \) denotes the consumption. In our framework both \( \delta \) and \( \gamma \) parameters are full information identifiable from the observed asset prices of the basic assets. Thus the discussion differs from the discussion in Stock, Wright (2000) in which the risk aversion parameter is assumed a priori weakly identified. In our framework the weak identification can only be the consequence of some lack of observations on derivative prices and concern some special risk premium parameters.

5.3 Nonparametric efficiency bounds

Two cases will be distinguished according to the type of information.

i) Limited information
The cross-sectional restrictions are:

\[ E[M_{t_0,t_0+1}(\theta) - 1|y_{t_0}] = 0, \]
\[ E[M_{t_0,t_0+1}(\theta) \exp r_{t_0+1} - 1|y_{t_0}] = 0, \]
\[ E[M_{t_0,t_0+1}(\theta) (\exp r_{t_0+1} - s)^+ - c_{t_0}(s)|y_{t_0}] = 0, \quad s = 0.98, 1, 1.02. \]

The conditional moments of interest are the prices of European calls at horizon 1:

\[ E(a(s)|y_{t_0}) = E\left[M_{t_0,t_0+1}(\theta) (\exp r_{t_0+1} - s)^+ |y_{t_0}\right], \quad \forall s. \]

The identifiable parameters are \( \nu_{t_0} = \nu_0 + \nu_2 \sigma_{t_0}^2, \nu_1, \nu_3. \) We provide in Figure 3 the nonparametric efficiency bound \( B(y_{t_0}, s) \) for \( E(a(s)|y_{t_0}) \) as a function of \( s. \)

[Insert Figure 3: Nonparametric efficiency bound, limited information]

The solid line corresponds to the call price \( E(a(s)|y_{t_0}) \), the dashed lines to confidence intervals \( E(a(s)|y_{t_0}) \pm 1.96 \frac{w}{\sqrt{Th_T^2}} \sigma_{t_0}^2 \), computed for \( w^2/Th_T^2 f_X(x_0) = 1 \). The current factor \( y_{t_0} \) corresponds to a variance \( \sigma_{t_0}^2 \) equal to the stationary expectation \( E\sigma_T^2 \). The width of the confidence interval for derivative price \( E(a(s)|y_{t_0}) \) depends on moneyness strike \( s. \) The interval is generally wider for almost at-the-money options, whereas it is narrower when the derivative is deep out- or deep in-the-money. Moreover the width of the interval is zero when \( s \) corresponds to the moneyness strikes of the observed calls.

To compare the results for derivatives with longer maturity, let us consider the nonparametric efficiency bound for a European call with residual maturity \( h = 60 \) days. At \( t_0 \) the prices of three derivatives with same residual maturity \( h = 60 \) and strikes \( s = 0.9, 1, 1.1 \), respectively, are assumed to be observed. In this case the whole parameter \( \theta \) is limited information identifiable. The efficiency bound is displayed in Figure 4 below.

[Insert Figure 4: Nonparam. eff. bound, limited information, maturity 60]

\[ ^{11}\text{We adopt this normalization to illustrate the pattern of the nonparametric efficiency bound as a function of the moneyness strike. The selection of empirically relevant sample size \( T \) and bandwidth \( h_T \) will be discussed in the next section, where we report the corresponding actual size of the efficiency bound.} \]
The confidence interval is larger for in-the-money strikes, and generally larger compared to maturity $h = 1$.

Note that the confidence intervals are pointwise confidence intervals. The choice of derivative prices corresponding to different strikes have in practice to be compatible with both a confidence band and also with the no arbitrage restrictions. This implies the selection of a decreasing convex function compatible with the band.

ii) **Mixed limited- and full-information**

Let us now consider the general approach with both uniform and conditional restrictions. The conditional moments of interest are still:

$$E(a(s)|y_{t_0}) = E[M_{t_0,t_0+1}(\theta) (\exp r_{t_0+1} - s)^+|y_{t_0}], \quad \forall s.$$ 

We check in Appendix 3 that Assumption A.2* is satisfied in the stochastic volatility framework. Matrix $R$ involved in Proposition 2 is given in equation (26). The nonparametric efficiency bound for a European call with residual maturity $h = 1$ is displayed in Figure 5.

[Insert Figure 5: Nonparametric efficiency bound, mixed information]

The confidence interval is similar to that obtained in the limited information framework (see Figure 3). To understand this fact, let us recall that, in the mixed case and at maturity 1, we have to estimate one parameter more than in the limited information case. This effect is approximately compensated by the contribution of the uniform restrictions.

In Figure 6 we display the mixed information nonparametric efficiency bound for a call option with residual maturity $h = 60$, when the price of three derivatives with same maturity and strikes $s = 0.9, 1, 1.1$, respectively, are observed.

[Insert Figure 6: Nonparam. eff. bound, mixed information, maturity 60]

The confidence band is more narrow than in the limited information case (see Figure 4). This is especially clear for in-the-money values of $s$ far from the observed strikes. The effect on the confidence interval is less clear close to observed strikes, or for rather deep out-of-the-money strikes. Indeed in these regions the option price is tight down from the observed prices, or has to be close to zero by definition, respectively.
Finally, in Figure 7 we display the mixed information nonparametric efficiency bound for a European call with maturity $h = 60$, when the prices of three derivatives with maturity 20 and strikes $s = 0.9, 1, 1.1$, respectively, are observed.

[Insert Figure 7: Nonparam. eff. bound, mixed information, maturity 60 and 20]

In this case the maturity of the observed derivatives does not correspond with the maturity of interest. This explains why the nonparametric efficiency bound is much larger compared with Figure 6, and in particular it is different from zero for all moneyness strikes. Observed derivative prices at the maturity of interest have a large informational content for the estimation of other derivative prices.

5.4 Monte-Carlo

In this section we report the results of Monte-Carlo simulations to investigate the finite sample properties of the information based estimator. Data are generated according to the ARG stochastic volatility model described in Section 5.1. We consider the general framework with both conditional and uniform restrictions.

At date $t_0$ the prices of three derivatives $c_{t_0}(h, s_k)$ with maturity $h = 2$ and moneyness strikes $s_k = 0.98, 1, 1.02$ are fixed. They are computed by simulation as explained in Section 5.1 with available information $\sigma_{t_0}^2 = E(\sigma_t^2)$. Then we simulate $S = 500$ paths of return-volatility process $(r_t, \sigma_t^2)$, $t = t_0 - T + 1, \ldots, t_0$, for sample size $T = 250$, such that the observed values at date $t_0$ are $r_{t_0} = 0$, $\sigma_{t_0}^2 = E(\sigma_t^2)$. Such paths are obtained by simulating the process backward. More precisely the time-discretized version of the Cox-Ingersoll-Ross process is time reversible. Therefore $(r_t, \sigma_t^2)$ follows the same stochastic volatility process both in direct and in reversed time. The information based estimator of structural parameter $\theta_0$ and of European call prices $E[a(h, s)|y_{t_0}]$ at date $t_0$ for maturity $h = 2$ and different strikes $s$ are computed for each simulated sample according to Section 3.2. The moment restrictions involve both the uniform no-arbitrage conditions from underlying asset returns and the conditional restrictions from observed derivative prices at date $t_0$. The kernel estimator of the conditional pdf is based on a Gaussian product kernel with different bandwidths for return and volatility,
which are equal to \( h_{r,T} = 0.0039 \) and \( h_{\sigma,T} = 0.0025 \), respectively\(^{12}\). Finally note that the selected sample size \( T = 250 \) corresponds to approximately 1 year of trading days, which is the sample length typically suggested by the regulator for risk management purposes.

i) Derivative prices

We display in Table 1 below the mean, the median, the 5% confidence interval, as well as the 5% and 95% quantiles of the estimated European call prices for maturity \( h = 2 \) and different values of the strike between \( s = 0.95 \) and \( s = 1.05 \).

[Table 1: Derivative prices, maturity 2, sample size 250]

For comparison we also report for each strike the corresponding true derivative price and the 5% asymptotic confidence interval based on the nonparametric efficiency bound, computed according to Section 5.3. As seen previously in Figures 5 and 6, the width of the nonparametric bound varies with the strike \( s \). In particular, the information content of the moment restrictions for estimating derivative prices can be very different across strikes. For instance the width of the confidence interval is less than 1% of the true price for strike \( s = 0.96 \), whereas it amounts to about 35% for strike \( s = 1.04 \).

Let us first consider the finite sample bias of estimated derivative prices. This bias is typically positive for ATM call options, whereas prices of OTM calls are generally underestimated. The corresponding relative pricing errors are less than 0.5% for strikes below \( s = 1.03 \), whereas it is about 5% for the deep OTM strikes.

Let us now consider the finite sample accuracy of the estimated derivative prices. The 5% confidence intervals and the 5% interquantile ranges of estimated call prices feature patterns across strikes similar to the patterns of the nonparametric efficiency bound, but they are wider. For instance, the 5% interquantile range is about 4% of the median (or mean) call price for strike \( s = 0.96 \), and about 135% for the deep OTM strike \( s = 1.04 \)\(^{13}\). In particular, these bounds are much larger than those typically reported in the literature based on fully parametric specifications. A narrow parametric

\(^{12}\) These bandwidths are selected in order to get an appropriate smoothing of the joint conditional pdf of \((r_t, \sigma_t)\) at sample size \( T = 250 \).

\(^{13}\) Note that for strike \( s = 1.04 \) the interquantile range is highly skewed, with the median very close to the lower bound.
bound however can be highly misleading in the presence of model misspecifications, that is when the true data generating process of underlying asset returns does not belong to the selected parametric family. In practice, the nonparametric bounds derived from the finite sample distribution of the information based estimator are likely to be preferred, since they provide more secure bounds for risk management purposes.

Finally, we display in Figure 8 the histograms of estimated derivative prices for different strikes.

[Figure 8: Histograms of estimated derivative prices]

These finite sample distributions feature non-Gaussian patterns, especially for deep ATM or deep OTM strikes, for which left, respectively right, skewed and fat tailed distributions are observed.

ii) Structural parameter

Although the focus of this paper is on estimation of the conditional moments corresponding to derivative prices, it is interesting to consider also the results for the estimator of structural parameter $\theta$. In Table 2 we display the mean, the median, the standard deviation and the 5% interquantile range of estimator $\hat{\theta}$.

[Table 2: Structural parameter, maturity 2, sample size 250]
The estimator of each component is downward biased for sample size $T = 250$, especially for parameters $\nu_0$, $\nu_1$, $\nu_2$. The medians are also below, but closer to, the true values $\theta_0$. The estimators feature large standard deviation and wide interquantile ranges. These results are confirmed by the histograms of the estimates, which are displayed in Figure 9.

[Figure 9: Histograms of estimated structural parameters]
The finite sample distributions of parameters $\nu_0$, $\nu_1$, $\nu_2$ are highly non-normal, in particular skewed to the left and with fat tails. The distribution of parameter $\nu_3$, instead, is closer to a Gaussian distribution. This difference in the patterns of the finite sample distributions reflects the different rates of convergence of the estimators, which are the parametric rate $T^{1/2}$ for $\nu_3$ and the nonparametric rate $(Th_{r,T}h_{\sigma,T})^{1/2}$ for $\nu_0$, $\nu_1$, $\nu_2$. These different rates of convergence are a consequence of market incompleteness, which cause parameters $\nu_0$, $\nu_1$, $\nu_2$ related to the risk premium for stochastic volatility to be full information non-identifiable.
6 Concluding remarks

The aim of this paper was to explain why the standard GMM approach is in general not appropriate for derivative pricing in an incomplete market framework, even if the stochastic discount factor is specified parametrically. Indeed in this framework it is necessary to distinguish the moment conditions which are uniform with respect to the conditioning variable and the restrictions which are valid for a given value of this variable. The extended method of moments explains how to mix appropriately these types of moment conditions. This implies different rates of convergence for the different parameters. In the derivative pricing application, the risk premium parameters are not necessarily identified from historical data, and some of them can only be deduced from less frequent cross-sectional observations on derivative prices. This implies different rates of convergence for the risk premia parameter, and approximations of derivative prices much less accurate than usually considered.

The analysis emphasizes on the notions of limited and full information identifiability, and the relationship between the degree of full information underidentifiability and the dimension of residual incompleteness in the application to derivative pricing. It differs from the standard GMM literature, which always assume full information identifiability.
APPENDIX 1

Semi-parametric efficiency bound

We derive below the expression of the semi-parametric efficiency bound by considering the linearization of the nonlinear constraints around the true value. The moment conditions defining the (kernel) moment estimator can be linearized around \( \theta = \theta_0 \):

\[
\begin{align*}
\sqrt{T} \tilde{E} [g_1(Y, X; \theta)] &\simeq \sqrt{T} \tilde{E} [g_1(Y, X; \theta_0)] + E_0 \left[ \frac{\partial g_1}{\partial \theta}(Y, X; \theta_0) \right] \sqrt{T} (\theta - \theta_0), \\
\sqrt{Th_1^d \tilde{E} [g_2(Y; \theta)|x_0]} &\simeq \sqrt{Th_1^d \tilde{E} [g_2(Y; \theta_0)|x_0]} + \sqrt{Th_1^d E_0} \left[ \frac{\partial g_2}{\partial \theta}(Y; \theta_0)|x_0 \right] (\theta - \theta_0), \\
\sqrt{Th_1^d \tilde{E} [a(\theta) - \beta|x_0]} &\simeq \sqrt{Th_1^d \tilde{E} [a(\theta_0)|x_0] - \beta_0|x_0] + \sqrt{Th_1^d E_0} \left[ \frac{\partial a}{\partial \theta}(Y; \theta_0)|x_0 \right] (\theta - \theta_0) \\
&- \sqrt{Th_1^d (\beta - \beta_0)}.
\end{align*}
\]

Let us introduce the change of parameters:

\[
\theta = \begin{pmatrix} \tilde{R} & R_Z \end{pmatrix} \begin{pmatrix} \eta_1 \\ \eta_2 \end{pmatrix}.
\]

Then we get:

\[
\begin{align*}
\sqrt{T} \tilde{E} [g_1(\theta)] &\simeq \sqrt{T} \tilde{E} (g_1) + E_0 \left( \frac{\partial g_1}{\partial \theta} \right) \tilde{R} \sqrt{T} (\eta_1 - \eta_1^0), \\
\sqrt{Th_1^d \tilde{E} [g_2(\theta)|x_0]} &\simeq \sqrt{Th_1^d \tilde{E} (g_2|x_0)} + \sqrt{h_1^d E_0} \left( \frac{\partial g_2}{\partial \theta}|x_0 \right) \tilde{R} \sqrt{T} (\eta_1 - \eta_1^0) \\
&+ E_0 \left( \frac{\partial g_2}{\partial \theta}|x_0 \right) R_Z \sqrt{Th_1^d (\eta_2 - \eta_2^0)}, \\
\sqrt{Th_1^d \tilde{E} [a(\theta) - \beta|x_0]} &\simeq \sqrt{Th_1^d \tilde{E} (a - \beta_0|x_0) + \sqrt{h_1^d E_0} \left( \frac{\partial a}{\partial \theta}|x_0 \right) \tilde{R} \sqrt{T} (\eta_1 - \eta_1^0) \\
&+ E_0 \left( \frac{\partial a}{\partial \theta}|x_0 \right) R_Z \sqrt{Th_1^d (\eta_2 - \eta_2^0) - \sqrt{Th_1^d (\beta - \beta_0)}}.
\end{align*}
\]

It is known that the moment estimator corresponding to the optimal weighting matrix is asymptotically equivalent to the GLS estimator of the linear
where the error term $U$ is zero-mean, with variance:

$$V(U) = \begin{pmatrix} V_1 & 0 \\ 0 & \Sigma \end{pmatrix},$$

where:

$$V_1 = \lim_{T \to \infty} V_0 \left[ \frac{1}{\sqrt{T}} \sum_{t=1}^{T} g_1(Y_t, X_t; \theta_0) \right], \quad \Sigma = \frac{1}{f_X(x_0)} \left( \begin{array}{cc} V_0(g_2|x_0) & Cov_0(g_2, a|x_0) \\ Cov_0(a, g_2|x_0) & V_0(a|x_0) \end{array} \right),$$

and the asymptotic correlation between the sample moment and the kernel estimator is zero. Thus estimators $\sqrt{T}(\tilde{\eta}_1 - \eta_1^0)$ and $\sqrt{Th_T^2}(\tilde{\eta}_2 - \eta_2^0, \hat{\beta} - \beta_0)$ are asymptotically normal, independent with asymptotic variances:

$$V_{as}\left[ \sqrt{T}(\tilde{\eta}_1 - \eta_1^0) \right] = \left[ \sqrt{T} E_0 \left( \frac{\partial g_1}{\partial \theta} \right) V_1^{-1} E_0 \left( \frac{\partial g_1}{\partial \theta} \right) \tilde{R} \right]^{-1},$$

and:

$$V_{as}\left[ \sqrt{Th_T^2}(\tilde{\eta}_2 - \eta_2^0, \hat{\beta} - \beta_0) \right] = \left[ \begin{array}{cc} E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) R_Z & 0 \\ E_0 \left( \frac{\partial a}{\partial \theta} | x_0 \right) R_Z & -Id \end{array} \right]^{-1} \Sigma^{-1} \left[ \begin{array}{cc} E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) R_Z & 0 \\ E_0 \left( \frac{\partial a}{\partial \theta} | x_0 \right) R_Z & -Id \end{array} \right],$$

respectively. In particular the semi-parametric efficiency bound is the lower $(L, L)$ block of matrix $V_{as}\left[ \sqrt{Th_T^2}(\tilde{\eta}_2 - \eta_2^0, \hat{\beta} - \beta_0) \right]$.  

39
APPENDIX 2

Information based estimator

The aim of this Appendix is to derive the asymptotic expansion of the objective function and of the estimators, in order to prove the asymptotic nonparametric efficiency of the information based estimator (Proposition 3).

i) Concentration with respect to functional parameter

Let us introduce Lagrange multipliers $\lambda_0, \mu_0, \lambda_t, \mu_t, \ t = 1, ..., T$. The Lagrangian function is given by:

$$L = \frac{1}{T} \sum_{t=1}^{T} \left[ \frac{\hat{f}(y|x_t) - f^t(y)}{\hat{f}(y|x_t)} \right]^2 dy + h_T^4 \int \log \left[ f^0(y)/\hat{f}(y|x_0) \right] f^0(y) dy$$

$$-2 \sum_{t=1}^{T} \mu_t \left( \int f^t(y) dy - 1 \right) - h_T^4 \mu_0 \left( \int f^0(y) dy - 1 \right)$$

$$-2 \sum_{t=1}^{T} \lambda_t \int g(y; \theta) f^t(y) dy - h_T^4 \lambda_0 \int g_2(y; \theta) f^0(y) dy.$$

The first order conditions w.r.t. functional parameters $f_t, \ t = 1, ..., T, f_0$ are:

$$\left[ f^t(y) - \hat{f}(y|x_t) \right] \frac{1}{\hat{f}(y|x_t)} - \mu_t - \lambda_t g(y; \theta) = 0, \quad t = 1, ..., T,$$

$$1 + \log \left( f^0(y)/\hat{f}(y|x_0) \right) - \mu_0 - \lambda_0 g_2(y; \theta) = 0,$$

that are:

$$f^t(y) = \hat{f}(y|x_t) + \mu_t \hat{f}(y|x_t) + \lambda_t g(y; \theta) \hat{f}(y|x_t), \quad t = 1, ..., T, \quad (A.1)$$

$$f^0(y) = \hat{f}(y|x_0) \exp \left( \lambda_0 g_2(y; \theta) + \mu_0 - 1 \right). \quad (A.2)$$

The Lagrange multipliers are deduced by the constraints. From (A.1) we get:

$$\int f^t(y) dy = 1 \iff \mu_t = -\lambda_t \int g(y; \theta) \hat{f}(y|x_t) dy,$$
and:
\[ \int g(y; \theta) f^t(y) \, dy = 0 \]
\[ \iff \int g(y; \theta) \hat{f}(y|x_t) \, dy + \int g(y; \theta) g(y; \theta) \dot{\hat{f}}(y|x_t) \, dy \cdot \lambda_t + \mu_t \int g(y; \theta) \hat{f}(y|x_t) \, dy = 0 \]
\[ \iff \lambda_t = -\left[ \int g(y; \theta) g(y; \theta) \dot{\hat{f}}(y|x_t) \, dy - \int g(y; \theta) \hat{f}(y|x_t) \, dy \int g(y; \theta) \dot{\hat{f}}(y|x_t) \, dy \right]^{-1} \cdot \int g(y; \theta) \hat{f}(y|x_t) \, dy, \quad t = 1, \ldots, T. \]

Similarly from (A.2) we deduce the value of Lagrange multiplier \( \mu_0 \):
\[ \int f^0(y) \, dy = 1 \iff \exp (1 - \mu_0) = \int e^{\lambda_0 g_2(y; \theta)} \hat{f}(y|x_0) \, dy. \]

Thus from (A.1), (A.2) \( \mu_0, \lambda_t, \mu_t, t = 1, \ldots, T \), can be eliminated to get the concentrated functional parameters:
\[ f^t(y; \theta) = \hat{f}(y|x_t) - \tilde{E}(g(\theta)|x_t) \dot{\hat{V}}(g(\theta)|x_t)^{-1} \left[ g(y; \theta) - \tilde{E}(g(\theta)|x_t) \right] \hat{f}(y|x_t), \quad t = 1, \ldots, T, \]
\[ f^0(y; \theta, \lambda_0) = \frac{\exp \lambda_0 g_2(y; \theta)}{E(\exp \lambda_0 g_2(\theta)|x_0)} \hat{f}(y|x_0), \]  \hspace{1cm} (A.3)

where \( \tilde{E}(.,|x) \) and \( \hat{V}(.,|x) \) denote the conditional expectation and the conditional variance w.r.t. the kernel density, respectively. The concentrated objective function becomes:
\[ L_c(\theta, \lambda_0) = \frac{1}{T} \sum_{t=1}^{T} \tilde{E}(g(\theta)|x_t) \dot{\hat{V}}(g(\theta)|x_t)^{-1} \tilde{E}(g(\theta)|x_t) \]
\[ - h^d_t \log \tilde{E} \left( \exp \lambda_0 g_2(\theta)|x_0 \right). \]

Then the information based estimator is such that \( \hat{\theta} \) is solution of the saddle point problem [see Kitamura-Stutzer (1997) in a marginal framework]:
\[ \hat{\theta} = \arg \min_{\theta} L_c(\theta, \lambda_0(\theta)), \]
where:
\[
\lambda_0(\theta) = \arg \max_{\lambda_0} \mathcal{L}_c(\theta, \lambda_0) \iff \tilde{E}\left(g_2(\theta) \exp \lambda_0(\theta) g_2(\theta) | x_0 \right) = 0,
\]
and the conditional density estimators are:
\[
\hat{f}_0(.|x_t) = f^t(\cdot; \hat{\theta}), \quad t = 1, ..., T,
\]
\[
\hat{f}_0(.|x_0) = f^0(\cdot; \hat{\theta}, \hat{\lambda}_0), \quad \hat{\lambda}_0 = \lambda_0(\theta).
\]

ii) Asymptotic expansion of the concentrated objective function

Since the conditional moment restrictions are satisfied asymptotically, we have \( \hat{\lambda}_0 \to 0 \) when \( T \to \infty \). Therefore we can consider the second order asymptotic expansion of function \( \mathcal{L}_c(\theta, \lambda_0) \) in a neighbourhood of \( \theta = \theta_0 \), \( \lambda_0 = 0 \). Let us first consider the expansion w.r.t. \( \lambda_0 \). We have:
\[
\log \tilde{E}\left(\exp \lambda_0' g_2(\theta) | x_0 \right) \\
\simeq \log \left[ 1 + \lambda_0' \tilde{E}\left(g_2(\theta) | x_0 \right) + \frac{1}{2} \lambda_0' \tilde{E}\left(g_2(\theta) g_2(\theta)' | x_0 \right) \lambda_0 \right] \\
\simeq \lambda_0' \tilde{E}\left(g_2(\theta) | x_0 \right) + \frac{1}{2} \lambda_0' \tilde{V}(g_2(\theta) | x_0) \lambda_0.
\]
Therefore we can asymptotically concentrate w.r.t. \( \lambda_0 \):
\[
\lambda_0 \simeq -\tilde{V}(g_2(\theta) | x_0)^{-1} \tilde{E}(g_2(\theta) | x_0), \tag{A.4}
\]
and the asymptotic expansion of the concentrated objective function becomes:
\[
\mathcal{L}_c(\theta) \simeq \frac{1}{T} \sum_{t=1}^{T} \tilde{E}\left(g(\theta)|x_t\right)' \tilde{V}(g(\theta)|x_t)^{-1} \tilde{E}(g(\theta)|x_t)
\]
\[
+ \frac{1}{2} h_{\theta}^\prime \tilde{E}(g_2(\theta)|x_0)' \tilde{V}(g_2(\theta)|x_0)^{-1} \tilde{E}(g_2(\theta)|x_0).
\]
Let us now consider the expansion around \( \theta = \theta_0 \). We have:
\[
\tilde{E}(g(\theta)|x_t) \simeq \tilde{E}(g(\theta_0)|x_t) + E_0 \left( \frac{\partial g}{\partial \theta}(\theta_0) \mid x_t \right) (\theta - \theta_0),
\]
42
\[ V(\theta | x_t) \simeq V_0(\theta_0 | x_t), \]
and similarly for the expectations of function \( g_2 \). Thus we get:

\[
\mathcal{L}_c(\theta) \simeq \frac{1}{T} \sum_{t=1}^T \left\{ \bar{E}\left( g|x_t \right) + E_0 \left( \frac{\partial g}{\partial \theta} | x_t \right) (\theta - \theta_0) \right\} V_0(\theta | x_t)^{-1} \\
\cdot \left\{ \bar{E}\left( g|x_t \right) + E_0 \left( \frac{\partial g}{\partial \theta} | x_t \right) (\theta - \theta_0) \right\} \\
+ \frac{1}{2} h_T^{d^T} \left\{ \bar{E}\left( g_2|x_0 \right) + E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) (\theta - \theta_0) \right\} V_0(g_2 | x_0)^{-1} \\
\cdot \left\{ \bar{E}\left( g_2|x_0 \right) + E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) (\theta - \theta_0) \right\},
\]

where functions \( g, g_2 \) are evaluated at \( \theta_0 \).

iii) Asymptotic expansion of \( \hat{\theta} \)

In order to derive the asymptotic expansion of \( \hat{\theta} \), we have to carefully distinguish the directions of \( \theta \) converging at a parametric rate [respectively at a nonparametric rate]. Let us introduce the change of parameter:

\[ \eta = R_1^{-1} \theta = \left( \eta_1', \eta_2' \right)', \]

where \( R_1 = \left[ \bar{R} \quad R \right] \) and \( R \) is a matrix whose columns span the null space \( N_0 \) [see Section 2.1.2]. Then we have:

\[ E_0 \left( \frac{\partial g}{\partial \theta} | x_t \right) (\theta - \theta_0) = E_0 \left( \frac{\partial g}{\partial \theta} | x_t \right) \bar{R} (\eta_1 - \eta_0^0). \]

We get:

\[
\mathcal{L}_c(\eta) \\
\simeq \frac{1}{T} \sum_{t=1}^T \left\{ \bar{E}\left( g|x_t \right) + E_0 \left( \frac{\partial g}{\partial \theta} | x_t \right) \bar{R} (\eta_1 - \eta_0^0) \right\} V_0(\theta | x_t)^{-1} \\
\cdot \left\{ \bar{E}\left( g|x_t \right) + E_0 \left( \frac{\partial g}{\partial \theta} | x_t \right) \bar{R} (\eta_1 - \eta_0^0) \right\} \\
+ \frac{1}{2} h_T^{d^T} \left\{ \bar{E}\left( g_2|x_0 \right) + E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) \bar{R} (\eta_1 - \eta_0^0) + E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) \bar{R} (\eta_2 - \eta_0^2) \right\} V_0(g_2 | x_0)^{-1} \\
\cdot \left\{ \bar{E}\left( g_2|x_0 \right) + E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) \bar{R} (\eta_1 - \eta_0^0) + E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) \bar{R} (\eta_2 - \eta_0^2) \right\}.
\]
The asymptotic expansion of $\hat{\eta}_1$ can be obtained from the maximization of the first term in $L_c(\eta)$ since the contribution of the second term is asymptotically negligible. We get:

$$\sqrt{T} (\hat{\eta}_1 - \eta_1^0) \approx - \left[ \frac{1}{\sqrt{T}} \sum_{t=1}^{T} \tilde{R} E_0 \left( \frac{\partial g_1'}{\partial \theta} | x_t \right) V_0 (g|x_t)^{-1} E_0 \left( \frac{\partial g_1'}{\partial \theta} | x_t \right) \tilde{R} \right]^{-1}$$

$$\cdot \frac{1}{\sqrt{T}} \sum_{t=1}^{T} \tilde{R} E_0 \left( \frac{\partial g_2'}{\partial \theta} | x_t \right) V_0 (g|x_t)^{-1} \int g(y; \theta_0) \hat{f}(y|x_t) dy.$$

Thus $\hat{\eta}_1$ converges at a parametric rate.

The asymptotic expansion of $\hat{\eta}_2$ can be deduced by the maximization of the second component of $L_c(\eta)$. Estimator $\hat{\eta}_2$ converges at a nonparametric rate and thus terms involving $(\hat{\eta}_1 - \eta_1^0)$ can be neglected. We get:

$$\langle \hat{\eta}_2 - \eta_2^0 \rangle \approx - \left[ R' E_0 \left( \frac{\partial g_2'}{\partial \theta} | x_0 \right) V_0 (g_2|x_0)^{-1} E_0 \left( \frac{\partial g_2'}{\partial \theta} | x_0 \right) R \right]^{-1}$$

$$\cdot R' E_0 \left( \frac{\partial g_2'}{\partial \theta} | x_0 \right) V_0 (g_2|x_0)^{-1} \int g_2(y; \theta_0) \hat{f}(y|x_0) dy.$$

(A.5)

iv) Asymptotic expansion of $\hat{f}_0(\cdot|x_0)$

Let us consider the expansion of $f^0(y; \theta, \lambda_0)$ in (A.3) around $\lambda_0 = 0$. We have:

$$f^0(y; \theta, \lambda_0) \approx \frac{1 + \lambda_0' g_2(y; \theta)}{1 + \lambda_0' \widehat{E} (g_2(\theta)|x_0)} \hat{f}(y|x_0)$$

$$\approx \left[ 1 + \lambda_0' \left( g_2(y; \theta) - \widehat{E} (g_2(\theta)|x_0) \right) \right] \hat{f}(y|x_0)$$

$$\approx \hat{f}(y|x_0) - \widehat{E} (g_2(\theta)|x_0) \hat{V} (g_2(\theta)|x_0)^{-1} \left( g_2(y; \theta) - \widehat{E} (g_2(\theta)|x_0) \right) \hat{f}(y|x_0),$$
from (A.4). Thus we get:

\[
\begin{align*}
\hat{f}_0(y|x_0) &= f_0(y; \hat{\theta}, \hat{\lambda}_0) \\
&\simeq \hat{f}(y|x_0) - \tilde{E} \left( g_2(\hat{\theta})|x_0 \right)^{\top} \tilde{V} \left( g_2(\hat{\theta})|x_0 \right)^{-1} \left( g_2(y; \hat{\theta}) - \tilde{E} \left( g_2(\hat{\theta})|x_0 \right) \right) \hat{f}(y|x_0) \\
&\simeq \hat{f}(y|x_0) - \tilde{E} \left( g_2(\hat{\theta})|x_0 \right)^{\top} V_0 (g_2|x_0)^{-1} g_2(y; \theta_0) f(y|x_0).
\end{align*}
\]

Moreover:

\[
\begin{align*}
\tilde{E} \left( g_2(\hat{\theta})|x_0 \right) &\simeq \int g_2(y; \theta_0) \hat{f}(y|x_0) dy + E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) (\hat{\theta} - \theta_0) \\
&\simeq \int g_2(y; \theta_0) \hat{f}(y|x_0) dy + E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) R (\hat{\eta}_2 - \eta_2^0) \\
&\quad \text{(since the contribution of } \hat{\eta}_1 - \eta_1^0 \text{ is asymptotically negligible)} \\
&= (Id - M) \int g_2(y; \theta_0) \hat{f}(y|x_0) dy,
\end{align*}
\]

from (A.5), where:

\[
M = E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) R \left[ R' E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) V_0 (g_2|x_0)^{-1} E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) R \right]^{-1} R' E_0 \left( \frac{\partial g_2}{\partial \theta} | x_0 \right) V_0 (g_2|x_0)^{-1},
\]

is an orthogonal projector for the inner product \( V_0 (g_2|x_0)^{-1} \). After replacing in (A.6) we get:

\[
\begin{align*}
\tilde{f}_0(y|x_0) &\simeq \hat{f}(y|x_0) - f(y|x_0) g_2(y; \theta_0)^{\top} V_0 (g_2|x_0)^{-1} (Id - M) \int g_2(y; \theta_0) \hat{f}(y|x_0) dy. \\
&\quad \text{(A.7)}
\end{align*}
\]

v) Asymptotic expansion of the moment of interest
We have:
\[
\hat{E}(a|x_0) = \int a(y; \hat{\theta}) \tilde{f}_0(y|x_0) dy
\]
\[
\simeq \int a(y; \theta_0) f(y|x_0) dy + \int \frac{\partial a}{\partial \theta}(y; \theta_0) f(y|x_0) dy (\hat{\theta} - \theta_0)
\]
\[
+ \int a(y; \theta_0) \left[ \tilde{f}_0(y|x_0) - f(y|x_0) \right] dy
\]
\[
\simeq E(a|x_0) + E_0 \left( \frac{\partial a}{\partial \theta}|x_0 \right) R (\tilde{\eta}_2 - \eta_2^0)
\]
\[
+ \int a(y; \theta_0) \left\{ \hat{f}(y|x_0) - f(y|x_0) - f(y|x_0) g_2(y; \theta_0) V_0(g_2|x_0)^{-1} \right\} dy [\text{from (A.7)}]
\]
\[
= E(a|x_0) - E_0 \left( \frac{\partial a}{\partial \theta}|x_0 \right) R \left[ R' E_0 \left( \frac{\partial g_2}{\partial \theta}|x_0 \right) V_0(g_2|x_0)^{-1} E_0 \left( \frac{\partial g_2}{\partial \theta}|x_0 \right) R \right]^{-1}
\]
\[
\cdot R' E_0 \left( \frac{\partial g_2}{\partial \theta}|x_0 \right) V_0(g_2|x_0)^{-1} \int g_2(y; \theta_0) \hat{f}(y|x_0) dy [\text{from (A.5)}]
\]
\[
+ \int a(y; \theta_0) \left[ \hat{f}(y|x_0) - f(y|x_0) \right] dy
\]
\[
- Cov_0(a, g_2|x_0) V_0(g_2|x_0)^{-1} (Id - M) \int g_2(y; \theta_0) \hat{f}(y|x_0) dy.
\]
Thus we get:
\[
\hat{E}(a|x_0) - E(a|x_0)
\]
\[
\simeq \int a(y; \theta_0) \delta \hat{f}(y|x_0) dy - Cov_0(a, g_2|x_0) V_0(g_2|x_0)^{-1} \int g_2(y; \theta_0) \delta \hat{f}(y|x_0) dy
\]
\[
- \left[ E_0 \left( \frac{\partial a}{\partial \theta}|x_0 \right) R - Cov_0(a, g_2|x_0) V_0(g_2|x_0)^{-1} E_0 \left( \frac{\partial g_2}{\partial \theta}|x_0 \right) R \right]
\]
\[
\cdot R' E_0 \left( \frac{\partial g_2}{\partial \theta}|x_0 \right) V_0(g_2|x_0)^{-1} E_0 \left( \frac{\partial g_2}{\partial \theta}|x_0 \right) R \right]^{-1}
\]
\[
\cdot R' E_0 \left( \frac{\partial g_2}{\partial \theta}|x_0 \right) V_0(g_2|x_0)^{-1} \int g_2(y; \theta_0) \delta \hat{f}(y|x_0) dy,
\]
(A.8)
where $\delta \hat{f}(y|x_0) = \hat{f}(y|x_0) - f(y|x_0)$.  

46
vi) Asymptotic distribution of the estimator

Let us finally derive the asymptotic distribution of the conditional moment estimator \( \widehat{E}(a|x_0) \). In the asymptotic expansion (A.8), the first two terms involve the residual of the regression of \( f(a(y; \theta_0)\delta \widehat{f}(y|x_0)dy \) on \( f(g_2(y; \theta_0)\delta \widehat{f}(y|x_0)dy \). This residual is asymptotically independent of the third term. Thus we get:

\[
\frac{\sqrt{T}h_T}{w} \left[ \widehat{E}(a|x_0) - E(a|x_0) \right] \xrightarrow{d} N(0, W(x_0)/f_X(x_0)),
\]

where the asymptotic variance is such that:

\[
W(x_0) = V_0(a|x_0) - Cov_0(a, g_2|x_0) V_0(g_2|x_0)^{-1} Cov_0(g_2, a|x_0)
+ \left[ E_0 \left( \frac{\partial a}{\partial \theta} \right)|x_0 \right] R - Cov_0(a, g_2|x_0) V_0(g_2|x_0)^{-1} E_0 \left( \frac{\partial g_2}{\partial \theta} \right)|x_0 \right] R \right]
\cdot \left[ R' E_0 \left( \frac{\partial g_2'}{\partial \theta} \right)|x_0 \right] V_0(g_2|x_0)^{-1} E_0 \left( \frac{\partial g_2}{\partial \theta} \right)|x_0 \right] R \right]^{-1}
\cdot \left[ E_0 \left( \frac{\partial a}{\partial \theta} \right)|x_0 \right] R - Cov_0(a, g_2|x_0) V_0(g_2|x_0)^{-1} E_0 \left( \frac{\partial g_2}{\partial \theta} \right)|x_0 \right] R \right]'.
\]

Since \( W(x_0)/f_X(x_0) \) corresponds to the (kernel) nonparametric efficiency bound \( B(x_0, a) \) [see Proposition 2], the (kernel) nonparametric efficiency of the information based estimator is proved.
APPENDIX 3

Identifiability in stochastic volatility model

In this Appendix we consider the identifiability of structural parameter $\theta$ in the stochastic volatility model. Specifically we check Assumption A.2* and provide the expression of matrix $R$ defining the directions of full information underidentification.

i) Computation of matrix $R$

The null space $N_0$ associated with the uniform restrictions is the linear space of vectors $v \in \mathbb{R}^4$ such that:

$$E_0 \left( \begin{pmatrix} 1 \\ \exp r_{t+1} \end{pmatrix} \frac{\partial M_{t,t+1}}{\partial \theta}(\theta_0) | y_t \right) v = 0, \quad \forall y_t. \quad (A.9)$$

We know that $\theta_0$ satisfies the no-arbitrage restrictions:

$$E_0 \left( M_{t,t+1}(\theta_0) \begin{pmatrix} 1 \\ \exp r_{t+1} \end{pmatrix} | y_t \right) = \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \quad \forall y_t.$$ 

We deduce that any $\theta = \theta_0 + v\varepsilon$, where $\varepsilon$ is small and $v$ satisfies (A.9), is also such that:

$$E_0 \left( M_{t,t+1}(\theta) \begin{pmatrix} 1 \\ \exp r_{t+1} \end{pmatrix} | y_t \right) = \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \quad \forall y_t;$$

at first order in $\varepsilon$. Therefore the vectors of $N_0$ are the directions $d\theta = \theta - \theta_0$ of parameter changes, which are compatible with no-arbitrage. From Proposition 4 and equations (24) the parameters $\theta$ which are compatible with no-arbitrage are characterized by the nonlinear restrictions:

$$\begin{align*}
\nu_0 &= -b (\nu_1 + \nu_3 \gamma - \nu_3^2 / 2), \\
\nu_2 &= -a (\nu_1 + \nu_3 \gamma - \nu_3^2 / 2), \\
\nu_3 &= \gamma + 1/2,
\end{align*}$$

where $\gamma$ is a parameter of the DGP considered as fixed. In particular, $\gamma = 1/2$ for the DGP considered in Section 5. Therefore:

$$\begin{align*}
\nu_0 &= -b (\nu_1), \\
\nu_2 &= -a (\nu_1), \\
\nu_3 &= 1.
\end{align*}$$
Thus the tangent set is spanned by the vector:

\[ v = \left( \begin{array}{c} \frac{d
u_0}{d\nu_1} \\ \frac{d
u_1}{d\nu_1} \\ \frac{d
u_2}{d\nu_1} \\ \frac{d
u_3}{d\nu_1} \end{array} \right) = \left( \begin{array}{c} -db(\nu_1)/d\nu_1 \\ 1 \\ -da(\nu_1)/d\nu_1 \\ 0 \end{array} \right) = \left( \begin{array}{c} -\delta \frac{c}{1+cv_1} \\ 1 \\ -\rho \frac{1}{(1+cv_1)^2} \\ 0 \end{array} \right). \]

Therefore matrix \( R \) is given by:

\[
R = \left( \begin{array}{cccc} -\delta \frac{c}{1+cv_1} \\ 1 \\ -\rho \frac{1}{(1+cv_1)^2} \\ 0 \end{array} \right). \tag{A.10}
\]

ii) Check of Assumption A.2

Let us now verify that Assumption A.2* is satisfied when the conditional restrictions include the observed price of a European call. We have to prove that:

\[
E_0 \left( \frac{\partial M_{t+1}}{\partial \theta} (\theta_0) \left( \exp r_{t+1} - s \right)^{+} \mid y_0 \right) R \neq 0, \quad \forall s > 0.
\]

In fact we have:

\[
E_0 \left( \frac{\partial M_{t+1}}{\partial \theta} (\theta_0) \left( \exp r_{t+1} - s \right)^{+} \mid y_0 \right) R = -E_0 \left( M_{t+1} (\theta_0) (\exp r_{t+1} - s)^{+} (1, \sigma_{t+1}^2, \sigma_{t+1}^2) R \mid y_0 \right)
\]

\[
= \left[ \delta \frac{c}{1+cv_1} + \rho \frac{1}{(1+cv_1)^2} \sigma_t^2 \right] E_0 \left( M_{t+1} (\theta_0) (\exp r_{t+1} - s)^{+} \mid y_0 \right)
\]

\[
- E_0 \left( M_{t+1} (\theta_0) (\exp r_{t+1} - s)^{+} \sigma_{t+1}^2 \mid y_0 \right).
\]

From (25) we have:

\[
\delta \frac{c}{1+cv_1} + \rho \frac{1}{(1+cv_1)^2} \sigma_t^2 = \rho^* \sigma_t^2 + \delta^* c^* = Q E_0 \left[ \sigma_{t+1}^2 \right],
\]

where \( Q \) denotes the risk neutral distribution, whereas from the Hull-White formula:

\[
E_0 \left( M_{t+1} (\theta_0) (\exp r_{t+1} - s)^{+} \mid y_0 \right) = \frac{Q}{E_{t_0}} \left[ BS \left( 1, s, \sigma_{t+1}^2 \right) \right],
\]

\[
E_0 \left( M_{t+1} (\theta_0) (\exp r_{t+1} - s)^{+} \sigma_{t+1}^2 \mid y_0 \right) = \frac{Q}{E_{t_0}} \left[ \sigma_{t+1}^2 BS \left( 1, s, \sigma_{t+1}^2 \right) \right].
\]
Thus we get:

\[
E_0 \left( \frac{\partial M_{t,t+1}}{\partial \theta} (\theta_0) (\exp r_{t+1} - s)^+ | y_{t0} \right) R = -Q \text{Cov}_t \left[ \sigma_{t+1}^2, BS (1, s, \sigma_{t+1}^2) \right],
\]

which is negative since the Black-Scholes price is an increasing function of volatility.
